Abstract:
Day-to-day variability in the F-region ionosphere has been attributed to three sources: the solar flux variation, geomagnetic activity, and lower atmospheric forcing. It is difficult to evaluate the roles of these sources, but recently, our understanding of the mechanism as well as our modelling capability to incorporate the lower atmospheric forcing have significantly improved. These can be attributed to numerous recent studies on Sudden Stratospheric Warming (SSW) events. To analyze the SSW event of January 2009, we have to look at the NmF2 (F-region peak electron density) and the hmF2 (height of F-region peak electron density) observed datasets from the NGDC. We will compare these observed datasets with two models, the International Reference Ionosphere (IRI) model, which is an empirical model, and the Ionosphere-Plasmasphere Electrodynamics (IPE) model, which is a physics based model. In comparing the variability between the observations and the model, we will be able to more effectively quantify the role of the lower atmospheric forcing.

Sudden Stratospheric Warming (SSW):
A SSW is a huge meteorological event where the westerlies in the Northern Hemisphere either reverse directions abruptly or slow down significantly. The polar vortex will weaken or even break down completely. The warming aspect comes from a rise in stratospheric temperature by tens of degrees. A key mechanism in SSW events is the propagation of planetary waves upward from the troposphere and their corresponding non-linear interaction with the zonal mean flow. The potential benefit of this connection is the ability to predict the SSW a few days in advance, allowing for potential ionospheric forecasting.

Ionosphere:
The ionosphere is a casing of free electrons and ions that surrounds the earth from roughly 60 km to 800 km. There are two regions in the ionosphere of note, but for the purposes of this research, the focus will be on the F2 region (Figure 1). Focusing on the F2 region is critical because it is furthest away from the recombination effects that could potentially concever the lower atmospheric forcing effects. The F2 region is driven by dynamics, more so than chemistry. NmF2 and hmF2 (Figure 2) are two parameters that can be indicative of the large scale structure of the ionosphere.

Results:
We plotted NmF2 and hmF2 once for each month (Jan 2009, Feb 2009, Dec 2008) and once for each location, Boulder (40°S, 105°W) and Jicamarca (12°S, 76°W), along with an average line plotted with the standard deviation at each point or time step (every 15 minutes).

Methodology:
NOAA’s National Centers for Environmental Information, formerly the National Geophysical Center (NGDC) provides archived Ionosonde Data for the public. Through the Space Physics Interactive Data Resource (SPIDR) portion of the NGDC, they provide ionosonde data across the world. There is no quality scan before this data gets disseminated, providing additional challenges in understanding the data. Here are some examples of the raw data plotted, with clearly anomalous points:

Quality Scanning:
To quality scan this dataset, we had to go back to look at the original ionogram images from which the NmF2 and hmF2 values have been obtained. By going through the data and selecting suspicious points, the timestamp of the point can be used to find the specific ionogram that is associated with the anomalous data point.

Conclusions:
We have determined the importance of quality scanning data in order to make sense of the findings. When comparing the IPE model and observed data, we see significant similarities. This means that with the WAM model driving the IPE model, the IPE model can accurately depict past events, and thus may be able to forecast events in the future. When it comes to the variation in electron density, the IPE model can reduce the variability and may be able to quantify the effects of lower atmospheric forcing. We also did compare an increase in electron density at low latitudes compared to mid latitudes.

Future Work:
To continue this research more effectively, a code must be written to take out anomalous points from observed data. Then we will continue running the IPE model for multiple days and multiple stations to compare the variability with the goal of quantifying the variability of electron density.

In the NmF2 plot, it is clear that the large spike in the data is anomalous and there are numerous anomalous points in the hmF2 plot as well (note: UT time here). Since there is no quality scan in the data, it must be done manually to get rid of the variation in the plots.
