STELLAR STRUCTURE AND EVOLUTION

O.R. Pols

Astronomical Institute Utrecht
September 2011
Preface

These lecture notes are intended for an advanced astrophysics course on Stellar Structure and Evolution given at Utrecht University (NS-AP434M). Their goal is to provide an overview of the physics of stellar interiors and its application to the theory of stellar structure and evolution, at a level appropriate for a third-year Bachelor student or beginning Master student in astronomy. To a large extent these notes draw on the classical textbook by Kippenhahn & Weigert (1990; see below), but leaving out unnecessary detail while incorporating recent astrophysical insights and up-to-date results. At the same time I have aimed to concentrate on physical insight rather than rigorous derivations, and to present the material in a logical order, following in part the very lucid but somewhat more basic textbook by Prialnik (2000). Finally, I have borrowed some ideas from the textbooks by Hansen, Kawaler & Trimble (2004), Salaris & Cassisi (2005) and the recent book by Maeder (2009).

These lecture notes are evolving and I try to keep them up to date. If you find any errors or inconsistencies, I would be grateful if you could notify me by email (O.R.Pols@uu.nl).

Onno Pols
Utrecht, September 2011

Chapter 1

Introduction

This introductory chapter sets the stage for the course, and briefly repeats some concepts from earlier courses on stellar astrophysics (e.g. the Utrecht first-year course *Introduction to stellar structure and evolution* by F. Verbunt).

The goal of this course on stellar evolution can be formulated as follows:

> to understand the structure and evolution of stars, and their observational properties, using known laws of physics

This involves applying and combining ‘familiar’ physics from many different areas (e.g. thermodynamics, nuclear physics) under extreme circumstances (high temperature, high density), which is part of what makes studying stellar evolution so fascinating.

What exactly do we mean by a ‘star’? A useful definition for the purpose of this course is as follows: a star is an object that (1) radiates energy from an internal source and (2) is bound by its own gravity. This definition excludes objects like planets and comets, because they do not comply with the first criterion. In the strictest sense it also excludes brown dwarfs, which are not hot enough for nuclear fusion, although we will briefly discuss these objects. (The second criterion excludes trivial objects that radiate, e.g. glowing coals).

An important implication of this definition is that stars must evolve (why?). A star is born out of an interstellar (molecular) gas cloud, lives for a certain amount of time on its internal energy supply, and eventually dies when this supply is exhausted. As we shall see, a second implication of the definition is that stars can have only a limited range of masses, between ~0.1 and ~100 times the mass of the Sun. The *life and death* of stars forms the subject matter of this course. We will only briefly touch on the topic of *star formation*, a complex and much less understood process in which the problems to be solved are mostly very different than in the study of stellar evolution.

1.1 Observational constraints

Fundamental properties of a star include the mass $M$ (usually expressed in units of the solar mass, $M_\odot = 1.99 \times 10^{33}$ g), the radius $R$ (often expressed in $R_\odot = 6.96 \times 10^{10}$ cm) and the luminosity $L$, the rate at which the star radiates energy into space (often expressed in $L_\odot = 3.84 \times 10^{33}$ erg/s). The effective temperature $T_{\text{eff}}$ is defined as the temperature of a black body with the same energy flux at the surface of the star, and is a good measure for the temperature of the photosphere. From the definition of effective temperature it follows that

$$L = 4\pi R^2 \sigma T_{\text{eff}}^4. \quad (1.1)$$
In addition, we would like to know the chemical composition of a star. Stellar compositions are usually expressed as mass fractions $X_i$, where $i$ denotes a certain element. This is often simplified to specifying the mass fractions $X$ (of hydrogen), $Y$ (of helium) and $Z$ (of all heavier elements or ‘metals’), which add up to unity. Another fundamental property is the rotation rate of a star, expressed either in terms of the rotation period $P_{\text{rot}}$ or the equatorial rotation velocity $\nu_{\text{eq}}$.

Astronomical observations can yield information about these fundamental stellar quantities:

- **Photometric measurements** yield the apparent brightness of a star, i.e. the energy flux received on Earth, in different wavelength bands. These are usually expressed as magnitudes, e.g. $B$, $V$, $I$, etc. Flux ratios or colour indices ($B - V$, $V - I$, etc.) give a measure of the effective temperature, using theoretical stellar atmosphere models and/or empirical relations. Applying a bolometric correction (which also depends on $T_{\text{eff}}$) yields the apparent bolometric flux, $f_{\text{bol}}$ (in erg s$^{-1}$ cm$^{-2}$).

- In some cases the distance $d$ to a star can be measured, e.g. from the parallax. The Hipparcos satellite has measured parallaxes with 1 milliarcsec accuracy of more than $10^5$ stars. The luminosity then follows from $L = 4\pi d^2 f_{\text{bol}}$, and the radius from eq. (1.1) if we have a measure of $T_{\text{eff}}$.

- An independent measure of the effective temperature can be obtained from interferometry. This technique yields the angular diameter of a star if it is sufficiently extended on the sky, i.e. the ratio $\theta = R/d$. Together with a measurement of $f_{\text{bol}}$ this can be seen from eq. (1.1) to yield $\sigma T_{\text{eff}}^4 = f_{\text{bol}}/\theta^2$. This technique is applied to red giants and supergiants. If the distance is also known, a direct measurement of the radius is possible.

- **Spectroscopy** at sufficiently high resolution yields detailed information about the physical conditions in the atmosphere. With detailed spectral-line analysis using stellar atmosphere models one can determine the photospheric properties of a star: the effective temperature and surface gravity ($g = GM/R^2$, usually expressed as log $g$), surface abundances of various elements (usually in terms of number density relative to hydrogen) and a measure of the rotation velocity ($\nu_{\text{eq}} \sin i$, where $i$ is the unknown inclination angle of the equatorial plane). In addition, for some stars the properties of the stellar wind can be determined (wind velocities, mass loss rates). All this is treated in more detail in the Master course on Stellar Atmospheres.

- The most important fundamental property, the mass, cannot be measured directly for a single star. To measure stellar masses one needs binary stars showing radial velocity variations (spectroscopic binaries). Radial velocities alone can only yield masses up to a factor $\sin i$, where $i$ is the inclination angle of the binary orbit. To determine absolute mass values one needs information on $i$, either from a visual orbit (visual binaries) or from the presence of eclipses (eclipsing binaries). In particular for so called double-lined eclipsing binaries, in which the spectral lines of both stars vary, it is possible to accurately measure both the masses and radii (with $1\text{--}2\%$ accuracy in some cases) by fitting the radial-velocity curves and the eclipse lightcurve. Together with a photometric or, better, spectroscopic determination of $T_{\text{eff}}$ also the luminosity of such binaries can be measured with high accuracy, independent of the distance. For more details see the Master course on Binary Stars.

All observed properties mentioned above are surface properties. Therefore we need a theory of stellar structure to derive the internal properties of a star. However, some direct windows on the interior of a star exist:
Figure 1.1. H-R diagram of solar neighbourhood. Source: Hipparcos, stars with \( d \) measured to < 10\% accuracy.

- **neutrinos**, which escape from the interior without interaction. So far, the Sun is the only (non-exploding) star from which neutrinos have been detected.

- **oscillations**, i.e. stellar seismology. Many stars oscillate, and their frequency spectrum contains information about the speed of sound waves inside the star, and therefore about the interior density and temperature profiles. This technique has provided accurate constraints on detailed structure models for the Sun, and is now also being applied to other stars.

The timespan of any observations is much smaller than a stellar lifetime: observations are like snapshots in the life of a star. The observed properties of an individual star contain no (direct) information about its evolution. The diversity of stellar properties (radii, luminosities, surface abundances) does, however, depend on how stars evolve, as well as on intrinsic properties (mass, initial composition). Properties that are common to a large number of stars must correspond to long-lived evolution phases, and vice versa. By studying samples of stars statistically we can infer the (relative) lifetimes of certain phases, which provides another important constraint on the theory of stellar evolution.

Furthermore, observations of samples of stars reveal certain correlations between stellar properties that the theory of stellar evolution must explain. Most important are relations between luminosity and effective temperature, as revealed by the Hertzsprung-Russell diagram, and relations between mass, luminosity and radius.

1.1.1 The Hertzsprung-Russell diagram

The Hertzsprung-Russell diagram (HRD) is an important tool to test the theory of stellar evolution. Fig. 1.1 shows the colour-magnitude diagram (CMD) of stars in the vicinity of the Sun, for which the Hipparcos satellite has measured accurate distances. This is an example of a volume-limited sample
of stars. In this observers’ HRD, the absolute visual magnitude $M_V$ is used as a measure of the luminosity and a colour index ($B - V$ or $V - I$) as a measure for the effective temperature. It is left as an exercise to identify various types of stars and evolution phases in this HRD, such as the main sequence, red giants, the horizontal branch, white dwarfs, etc.

Star clusters provide an even cleaner test of stellar evolution. The stars in a cluster were formed within a short period of time (a few Myr) out of the same molecular cloud and therefore share the same age and (initial) chemical composition.\(^{1}\) Therefore, to first-order approximation only the mass varies from star to star. A few examples of cluster CMDs are given in Fig. 1.2, for a young open cluster (the Pleiades) and an old globular cluster (M3). As the cluster age increases, the most luminous main-sequence stars disappear and a prominent red giant branch and horizontal branch appear. To explain the morphology of cluster HRDs at different ages is one of the goals of studying stellar evolution.

1.1.2 The mass-luminosity and mass-radius relations

For stars with measured masses, radii and luminosities (i.e. binary stars) we can plot these quantities against each other. This is done in Fig. 1.3 for the components of double-lined eclipsing binaries for which $M$, $R$ and $L$ are all measured with $\lesssim 2\%$ accuracy. These quantities are clearly correlated, and especially the relation between mass and luminosity is very tight. Most of the stars in Fig. 1.3 are long-lived main-sequence stars; the spread in radii for masses between 1 and 2 $M_\odot$ results from the fact that several more evolved stars in this mass range also satisfy the 2\% accuracy criterion. The observed relations can be approximated reasonably well by power laws:

$$L \propto M^{3.8}, \quad R \propto M^{0.7}.$$  \hspace{1cm} (1.2)

Again, the theory of stellar evolution must explain the existence and slopes of these relations.

\(^{1}\)The stars in a cluster thus constitute a so-called simple stellar population. Recently, this simple picture has changed somewhat after the discovery of multiple populations in many star clusters.
1.2 Stellar populations

Stars in the Galaxy are divided into different populations:

- Population I: stars in the galactic disk, in spiral arms and in (relatively young) open clusters. These stars have ages $\lesssim 10^9$ yr and are relatively metal-rich ($Z \sim 0.5 - 1 Z_\odot$).
- Population II: stars in the galactic halo and in globular clusters, with ages $\sim 10^{10}$ yr. These stars are observed to be metal-poor ($Z \sim 0.01 - 0.1 Z_\odot$).

An intermediate population (with intermediate ages and metallicities) is also seen in the disk of the Galaxy. Together they provide evidence for the chemical evolution of the Galaxy: the abundance of heavy elements ($Z$) apparently increases with time. This is the result of chemical enrichment by subsequent stellar generations.

The study of chemical evolution has led to the hypothesis of a ‘Population III’ consisting of the first generation of stars formed after the Big Bang, containing only hydrogen and helium and no heavier elements (‘metal-free’, $Z = 0$). No metal-free stars have ever been observed, probably due to the fact that they were massive and had short lifetimes and quickly enriched the Universe with metals. However, a quest for finding their remnants has turned up many very metal-poor stars in the halo, with the current record-holder having an iron abundance $X_{\text{Fe}} = 4 \times 10^{-6} X_{\text{Fe,\odot}}$.

1.3 Basic assumptions

We wish to build a theory of stellar evolution to explain the observational constraints highlighted above. In order to do so we must make some basic assumptions:

- stars are considered to be isolated in space, so that their structure and evolution depend only on intrinsic properties (mass and composition). For most single stars in the Galaxy this condition is satisfied to a high degree (compare for instance the radius of the Sun with the distance to its
nearest neighbour Proxima Centauri, see exercise 1.2). However, for stars in dense clusters, or in binary systems, the evolution can be influenced by interaction with neighbouring stars. In this course we will mostly ignore these complicating effects (many of which are treated in the Master course on *Binary Stars*).

- stars are formed with a *homogeneous composition*, a reasonable assumption since the molecular clouds out of which they form are well-mixed. We will often assume a so-called ‘quasi-solar’ composition \((X = 0.70, Y = 0.28\) and \(Z = 0.02\)), even though recent determinations of solar abundances have revised the solar metallicity down to \(Z = 0.014\). In practice there is relatively little variation in composition from star to star, so that the initial mass is the most important parameter that determines the evolution of a star. The composition, in particular the metallicity \(Z\), is of secondary influence but can have important effects especially in very metal-poor stars (see § 1.2).

- *spherical symmetry*, which is promoted by self-gravity and is a good approximation for most stars. Deviations from spherical symmetry can arise if non-central forces become important relative to gravity, in particular rotation and magnetic fields. Although many stars are observed to have magnetic fields, the field strength (even in highly magnetized neutron stars) is always negligible compared to gravity. Rotation can be more important, and the *rotation rate* can be considered an additional parameter (besides mass and composition) determining the structure and evolution of a star. For the majority of stars (e.g. the Sun) the forces involved are small compared to gravity. However, some rapidly rotating stars are seen (by means of interferometry) to be substantially flattened.

### 1.4 Aims and overview of the course

In the remainder of this course we will:

- understand the global properties of stars: energetics and timescales
- study the micro-physics relevant for stars: the equation of state, nuclear reactions, energy transport and opacity
- derive the equations necessary to model the internal structure of stars
- examine (quantitatively) the properties of simplified stellar models
- survey (mostly qualitatively) how stars of different masses evolve, and the endpoints of stellar evolution (white dwarfs, neutron stars)
- discuss a few ongoing research areas in stellar evolution

---

**Suggestions for further reading**

The contents of this introductory chapter are also largely covered by Chapter 1 of *Prialnik*, which provides nice reading.
Exercises

1.1 Evolutionary stages

In this course we use many concepts introduced in the introductory astronomy classes. In this exercise we recapitulate the names of evolutionary phases. During the lectures you are assumed to be familiar with these terms, in the sense that you are able to explain them in general terms.

We encourage you to use Carroll & Ostlie, Introduction to Modern Astrophysics, or the book of the first year course (Verbunt, Het leven van sterren) to make a list of the concepts printed in italic with a brief explanation in your own words.

(a) Figure 1.1 shows the location of stars in the solar neighborhood in the Hertzsprung-Russel diagram. Indicate in Figure 1.1 where you would find:

- main-sequence stars,
- neutron stars,
- the Sun,
- black holes,
- red giants,
- binary stars,
- horizontal branch stars,
- planets,
- asymptotic giant branch (AGB) stars,
- pre-main sequence stars,
- central star of planetary nebulae,
- hydrogen burning stars,
- white dwarfs,
- helium burning stars.

(b) Through which stages listed above will the Sun evolve? Put them in chronological order. Through which stages will a massive star evolve?

(c) Describe the following concepts briefly in your own words. You will need the concepts indicated with * in the coming lectures.

- ideal gas*,
- Jeans mass,
- black body,
- Schwarzschild criterion,
- virial theorem*,
- energy transport by radiation,
- first law of thermodynamics*,
- energy transport by convection,
- equation of state,
- pp-chain,
- binary stars,
- CNO cycle,
- star cluster; nuclear timescale*,
- interstellar medium; thermal or Kelvin-Helmholtz timescale*,
- giant molecular clouds; dynamical timescale*

1.2 Basic assumptions

Let us examine the three basic assumptions made in the theory of stellar evolution:

(a) Stars are assumed to be isolated in space. The star closest to the sun, Proxima Centauri, is 4.3 light-years away. How many solar radii is that? By what factors are the gravitational field and the radiation flux diminished? Many stars are formed in clusters and binaries. How could that influence the life of a star?

(b) Stars are assumed to form with a uniform composition. What elements is the Sun made of? Just after the Big Bang the Universe consisted almost purely of hydrogen and helium. Where do all the heavier elements come from?

(c) Stars are assumed to be spherically symmetric. Why are stars spherically symmetric to a good approximation? How would rotation affect the structure and evolution of a star? The Sun rotates around its axis every 27 days. Calculate the ratio of is the centrifugal acceleration $a$ over the gravitational acceleration $g$ for a mass element on the surface of the Sun. Does rotation influence the structure of the Sun?

1.3 Mass-luminosity and mass-radius relation

(a) The masses of stars are approximately in the range $0.08 M_\odot \lesssim M \lesssim 100 M_\odot$. Why is there an upper limit? Why is there a lower limit?
(b) Can you think of methods to measure (1) the mass, (2) the radius, and (3) the luminosity of a star? Can your methods be applied for any star or do they require special conditions. Discuss your methods with your fellow students.

(c) Figure 1.3 shows the luminosity versus the mass (left) and the radius versus the mass (right) for observed main sequence stars. We can approximate a mass-luminosity and mass-radius relation by fitting functions of the form

\[
\frac{L}{L_\odot} = \left(\frac{M}{M_\odot}\right)^x, \quad \frac{R}{L_\odot} = \left(\frac{M}{M_\odot}\right)^y
\]

Estimate \(x\) and \(y\) from Figure 1.3.

(d) Which stars live longer, high mass stars (which have more fuel) or low mass stars? Derive an expression for the lifetime of a star as a function of its mass. (!)

[Hints: Stars spend almost all their life on the main sequence burning hydrogen until they run out of fuel. First try to estimate the lifetime as function of the mass (amount of fuel) and the luminosity (rate at which the fuel is burned).]

1.4 The ages of star clusters

The stars in a star cluster are formed more or less simultaneously by fragmentation of a large molecular gas cloud.

(a) In Fig. 1.4 the H-R diagrams are plotted of the stars in three different clusters. Which cluster is the youngest?

(b) Think of a method to estimate the age of the clusters, discuss with your fellow students. Estimate the ages and compare with the results of your fellow students.

(c) (*) Can you give an error range on your age estimates?
Chapter 2

Mechanical and thermal equilibrium

In this chapter we apply the physical principles of mass conservation and momentum conservation to derive two of the fundamental stellar structure equations. We shall see that stars are generally in a state of almost complete mechanical equilibrium, which allows us to derive and apply the important virial theorem. We consider the basic stellar timescales and see that most (but not all) stars are also in a state of energy balance called thermal equilibrium.

2.1 Coordinate systems and the mass distribution

The assumption of spherical symmetry implies that all interior physical quantities (such as density \( \rho \), pressure \( P \), temperature \( T \), etc) depend only on one radial coordinate. The obvious coordinate to use in a Eulerian coordinate system is the radius of a spherical shell, \( r (\in 0 \ldots R) \). In an evolving star, all quantities also depend on time \( t \). When constructing the differential equations for stellar structure one should thus generally consider partial derivatives of physical quantities with respect to radius and time, \( \partial / \partial r \) and \( \partial / \partial t \), taken at constant \( t \) and \( r \), respectively.

The principle of mass conservation applied to the mass \( dm \) of a spherical shell of thickness \( dr \) at radius \( r \) (see Fig. 2.1) gives

\[
\frac{dm(r, t)}{dr} = 4\pi r^2 \rho \ dr - 4\pi r^2 \rho \upsilon dt,
\]

where \( \upsilon \) is the radial velocity of the mass shell. Therefore one has

\[
\frac{dm}{dr} = 4\pi r^2 \rho \quad \text{and} \quad \frac{dm}{dt} = -4\pi r^2 \rho \upsilon.
\]

The first of these partial differential equations relates the radial mass distribution in the star to the local density: it constitutes the first fundamental equation of stellar structure. Note that \( \rho = \rho(r, t) \) is not known a priori, and must follow from other conditions and equations. The second equation of (2.2) represents the change of mass inside a sphere of radius \( r \) due to the motion of matter through its surface; at the stellar surface this gives the mass-loss rate (if there is a stellar wind with \( \upsilon > 0 \)) or mass-accretion rate (if there is inflow with \( \upsilon < 0 \)). In a static situation, where the velocity is zero, the first equation of (2.2) becomes an ordinary differential equation,

\[
\frac{dm}{dr} = 4\pi r^2 \rho.
\]

This is almost always a good approximation for stellar interiors, as we shall see. Integration yields the mass \( m(r) \) inside a spherical shell of radius \( r \):

\[
m(r) = \int_0^r 4\pi r'^2 \rho \ dr'.
\]
Since \( m(r) \) increases monotonically outward, we can also use \( m(r) \) as our radial coordinate, instead of \( r \). This mass coordinate, often denoted as \( m \), or simply \( m \), is a Lagrangian coordinate that moves with the mass shells:

\[
m := m_r = \int_0^r 4\pi r'^2 \rho \, dr' \quad (m \in 0 \ldots M).
\]  

(2.4)

It is often more convenient to use a Lagrangian coordinate instead of a Eulerian coordinate. The mass coordinate is defined on a fixed interval, \( m \in 0 \ldots M \), as long as the star does not lose mass. On the other hand \( r \) depends on the time-varying stellar radius \( R \). Furthermore the mass coordinate follows the mass elements in the star, which simplifies many of the time derivatives that appear in the stellar evolution equations (e.g. equations for the composition). We can thus write all quantities as functions of \( m \), i.e. \( r = r(m) \), \( \rho = \rho(m) \), \( P = P(m) \), etc.

Using the coordinate transformation \( r \rightarrow m \), i.e.

\[
\frac{\partial}{\partial m} = \frac{\partial}{\partial r} \cdot \frac{\partial r}{\partial m},
\]

(2.5)

the first equation of stellar structure becomes in terms of the coordinate \( m \):

\[
\frac{\partial r}{\partial m} = \frac{1}{4\pi r^2 \rho}
\]

(2.6)

which again becomes an ordinary differential equation in a static situation.

### 2.1.1 The gravitational field

Recall that a star is a self-gravitating body of gas, which implies that gravity is the driving force behind stellar evolution. In the general, non-spherical case, the gravitational acceleration \( g \) can be written as the gradient of the gravitational potential, \( g = -\nabla \Phi \), where \( \Phi \) is the solution of the Poisson equation

\[
\nabla^2 \Phi = 4\pi G \rho.
\]

Inside a spherically symmetric body, this reduces to \( g := |g| = d\Phi/dr \). The gravitational acceleration at radius \( r \) and equivalent mass coordinate \( m \) is then given by

\[
g = \frac{Gm}{r^2}.
\]

(2.7)
Spherical shells outside \( r \) apply no net force, so that \( g \) only depends on the mass distribution inside the shell at radius \( r \). Note that \( g \) is the magnitude of the vector \( \mathbf{g} \) which points inward (toward smaller \( r \) or \( m \)).

### 2.2 The equation of motion and hydrostatic equilibrium

We next consider conservation of momentum inside a star, i.e. Newton’s second law of mechanics. The net acceleration on a gas element is determined by the sum of all forces acting on it. In addition to the gravitational force considered above, forces result from the pressure exerted by the gas surrounding the element. Due to spherical symmetry, the pressure forces acting horizontally (perpendicular to the radial direction) balance each other and only the pressure forces acting along the radial direction need to be considered. By assumption we ignore other forces that might act inside a star (Sect. 1.3).

Hence the net acceleration \( \ddot{r} = \frac{\partial^2 r}{\partial t^2} \) of a (cylindrical) gas element with mass

\[
dm = \rho \, dr \, dS \tag{2.8}
\]

(\( dS \) is its horizontal surface area, see Fig. 2.1) is given by

\[
\dot{r} \, dm = -g \, dm + P(r) \, dS - P(r + dr) \, dS. \tag{2.9}
\]

We can write \( P(r + dr) = P(r) + (\partial P / \partial r) \cdot dr \), hence after substituting eqs. (2.7) and (2.8) we obtain the equation of motion for a gas element inside the star:

\[
\frac{\partial^2 r}{\partial t^2} = -\frac{Gm}{r^2} - \frac{1}{\rho} \frac{\partial P}{\partial r}. \tag{2.10}
\]

This is a simplified form of the Navier-Stokes equation of hydrodynamics, applied to spherical symmetry (see Mådèr). Writing the pressure gradient \( \partial P / \partial r \) in terms of the mass coordinate \( m \) by substituting eq. (2.6), the equation of motion is

\[
\frac{\partial^2 r}{\partial t^2} = -\frac{Gm}{r^2} - 4\pi r^2 \frac{\partial P}{\partial m}. \tag{2.11}
\]

**Hydrostatic equilibrium** The great majority of stars are obviously in such long-lived phases of evolution that no change can be observed over human lifetimes. This means there is no noticeable acceleration, and all forces acting on a gas element inside the star almost exactly balance each other. Thus most stars are in a state of mechanical equilibrium which is more commonly called **hydrostatic equilibrium** (HE).

The state of hydrostatic equilibrium, setting \( \ddot{r} = 0 \) in eq. (2.10), yields the second differential equation of stellar structure:

\[
\frac{dP}{dr} = -\frac{Gm}{r^2} \rho, \tag{2.12}
\]

or with eq. (2.6)

\[
\frac{dP}{dm} = -\frac{Gm}{4\pi r^4} \tag{2.13}
\]

A direct consequence is that inside a star in hydrostatic equilibrium, the pressure always decreases outwards.

Eqs. (2.6) and (2.13) together determine the **mechanical structure** of a star in HE. These are two equations for three unknown functions of \( m (r, P \) and \( \rho) \), so they cannot be solved without a
third condition. This condition is usually a relation between $P$ and $\rho$ called the \textit{equation of state} (see Chapter 3). In general the equation of state depends on the temperature $T$ as well, so that the mechanical structure depends also on the temperature distribution inside the star, i.e. on its thermal structure. In special cases the equation of state is independent of $T$, and can be written as $P = P(\rho)$. In such cases (known as barotropes or polytropes) the mechanical structure of a star becomes independent of its thermal structure. This is the case for white dwarfs, as we shall see later.

\textbf{Estimates of the central pressure}  

A rough order-of-magnitude estimate of the central pressure can be obtained from eq. (2.13) by setting

$$ \frac{dP}{dm} \sim \frac{P_{\text{surf}} - P_c}{M} \approx \frac{P_c}{M} \quad m \sim \frac{1}{2} M, \quad r \sim \frac{1}{2} R $$

which yields

$$ P_c \sim \frac{2GM^2}{\pi R^4} \quad (2.14) $$

For the Sun we obtain from this estimate $P_c \sim 7 \times 10^{15}$ dyn/cm$^2 = 7 \times 10^9$ atm.

A lower limit on the central pressure may be derived by writing eq. (2.13) as

$$ \frac{dP}{dr} = -\frac{Gm}{4\pi r^4} \frac{dm}{dr} = -\frac{d}{dr}(\frac{Gm^2}{8\pi r^4}) - \frac{Gm^2}{2\pi r^5}, $$

and thus

$$ \frac{d}{dr}(P + \frac{Gm^2}{8\pi r^4}) = -\frac{Gm^2}{2\pi r^5} < 0. \quad (2.15) $$

The quantity $\Psi(r) = P + \frac{Gm^2}{8\pi r^4}$ is therefore a decreasing function of $r$. At the centre, the second term vanishes because $m \propto r^3$ for small $r$, and hence $\Psi(0) = P_c$. At the surface, the pressure is essentially zero. From the fact that $\Psi$ must decrease with $r$ it thus follows that

$$ P_c > \frac{1}{8\pi} \frac{GM^2}{R^4}. \quad (2.16) $$

In contrast to eq. (2.14), this is a strict mathematical result, valid for any star in hydrostatic equilibrium regardless of its other properties (in particular, regardless of its density distribution). For the Sun we obtain $P_c > 4.4 \times 10^{14}$ dyn/cm$^2$. Both estimates indicate that an extremely high central pressure is required to keep the Sun in hydrostatic equilibrium. Realistic solar models show the central density to be $2.4 \times 10^{17}$ dyn/cm$^2$.

\subsection*{2.2.1 The dynamical timescale}

We can ask what happens if the state of hydrostatic equilibrium is violated: how fast do changes to the structure of a star occur? The answer is provided by the equation of motion, eq. (2.10). For example, suppose that the pressure gradient that supports the star against gravity suddenly drops. All mass shells are then accelerated inwards by gravity: the star starts to collapse in “free fall”. We can approximate the resulting (inward) acceleration by

$$ |\ddot{r}| \approx \frac{R}{\tau_{\text{ff}}^2} \quad \Rightarrow \quad \tau_{\text{ff}} \approx \sqrt{\frac{R}{|\ddot{r}|}} $$

where \( \tau_{ff} \) is the free-fall timescale that we want to determine. Since \( -\ddot{r} = g \approx GM/R^2 \) for the entire star, we obtain

\[
\tau_{ff} \approx \sqrt{\frac{R}{g}} \approx \sqrt{\frac{R^3}{GM}}.
\]

Of course each mass shell is accelerated at a different rate, so this estimate should be seen as an average value for the star to collapse over a distance \( R \). This provides one possible estimate for the dynamical timescale of the star. Another estimate can be obtained in a similar way by assuming that gravity suddenly disappears: this gives the timescale for the outward pressure gradient to explode the star, which is similar to the time it takes for a sound wave to travel from the centre to the surface of the star. If the star is close to HE, all these timescales have about the same value given by eq. (2.17).

Since the average density \( \bar{\rho} = 3M/(4\pi R^3) \), we can also write this (hydro)dynamical timescale as

\[
\tau_{dyn} \approx \sqrt{\frac{R^3}{GM}} \approx \frac{1}{2} (G\bar{\rho})^{-1/2}.
\]

For the Sun we obtain a very small value of \( \tau_{dyn} \approx 1600 \text{ sec or about half an hour (0.02 days)} \). This is very much smaller than the age of the Sun, which is 4.6 Gyr or \( \sim 1.5 \times 10^{17} \) sec, by 14 orders of magnitude. This result has several important consequences for the Sun and other stars:

- Any significant departure from hydrostatic equilibrium should very quickly lead to observable phenomena: either contraction or expansion on the dynamical timescale. If the star cannot recover from this disequilibrium by restoring HE, it should lead to a collapse or an explosion.

- Normally hydrostatic equilibrium can be restored after a disturbance (we will consider this dynamical stability of stars later). However a perturbation of HE may lead to small-scale oscillations on the dynamical timescale. These are indeed observed in the Sun and many other stars, with a period of minutes in the case of the Sun. Eq. (2.18) tells us that the pulsation period is a (rough) measure of the average density of the star.

- Apart from possible oscillations, stars are extremely close to hydrostatic equilibrium, since any disturbance is immediately quenched. We can therefore be confident that eq. (2.13) holds throughout most of their lifetimes. Stars do evolve and are therefore not completely static, but changes occur very slowly compared to their dynamical timescale. Stars can be said to evolve quasi-statically, i.e. through a series of near-perfect HE states.

### 2.3 The virial theorem

An important consequence of hydrostatic equilibrium is the virial theorem, which is of vital importance for the understanding of stars. It connects two important energy reservoirs of a star and allows predictions and interpretations of important phases in the evolution of stars.

To derive the virial theorem we start with the equation for hydrostatic equilibrium eq. (2.13). We multiply both sides by the enclosed volume \( V = \frac{4}{3}\pi r^3 \) and integrate over \( m \):

\[
\int_0^M \frac{4}{3}\pi r^3 \frac{dP}{dm} \, dm = -\frac{1}{3} \int_0^M \frac{Gm}{r} \, dm
\]

The integral on the right-hand side has a straightforward physical interpretation: it is the gravitational potential energy of the star. To see this, consider the work done by the gravitational force \( \mathbf{F} \) to bring a mass element \( \delta m \) from infinity to radius \( r \):

\[
\delta W = \int_{\infty}^{r} \mathbf{F} \cdot d\mathbf{r} = \int_{\infty}^{r} \frac{Gm}{r^2} \delta m \, dr = -\frac{GM}{r} \delta m.
\]
The gravitational potential energy of the star is the work performed by the gravitational force to bring all mass elements from infinity to their current radius, i.e.

\[ E_{\text{gr}} = -\int_0^M \frac{Gm}{r} \, dm \]  

(2.20)

The left-hand side of eq. (2.19) can be integrated by parts:

\[ \int_{P_c}^{P_s} V \, dP = \left[ V \cdot P \right]^s_c - \int_0^{V_s} P \, dV \]  

(2.21)

where \( c \) and \( s \) denote central and surface values. Combining the above expressions in eq. (2.19) we obtain

\[ \frac{4}{3} \pi R^3 P(R) - \int_0^{V_s} P \, dV = \frac{1}{2} E_{\text{gr}}, \]  

(2.22)

with \( P(R) \) the pressure at the surface of the volume. This expression is useful when the pressure from the surrounding layers is substantial, e.g. when we consider only the core of a star. If we consider the star as a whole, however, the first term vanishes because the pressure at the stellar surface is negligible. In that case

\[ -3 \int_0^{V_s} P \, dV = E_{\text{gr}}, \]  

(2.23)

or, since \( dV = dm/\rho \),

\[ -3 \int_0^M \frac{P}{\rho} \, dm = E_{\text{gr}}. \]  

(2.24)

This is the general form of the virial theorem, which will prove valuable later. It tells us that that the average pressure needed to support a star in HE is equal to \(-\frac{1}{3} E_{\text{gr}}/V\). In particular it tells us that a star that contracts quasi-statically (that is, slowly enough to remain in HE) must increase its internal pressure, since \(|E_{\text{gr}}|\) increases while its volume decreases.

### The virial theorem for an ideal gas

The pressure of a gas is related to its internal energy. We will show this in Ch. 3, but for the particular case of an ideal monatomic gas it is easy to see. The pressure of an ideal gas is given by

\[ P = nkT = \frac{\rho}{\mu m_u} kT, \]  

(2.25)

where \( n = N/V \) is the number of particles per unit volume, and \( \mu \) is mass of a gas particle in atomic mass units. The kinetic energy per particle is \( \epsilon_k = \frac{3}{2} kT \), and the internal energy of an ideal monatomic gas is equal to the kinetic energy of its particles. The internal energy per unit mass is then

\[ u = \frac{3}{2} \frac{kT}{\mu m_u} = \frac{3}{2} \frac{P}{\rho}. \]  

(2.26)

We can now interpret the left-hand side of the virial theorem (eq. 2.24) as \( \int (P/\rho) \, dm = \frac{2}{3} \int u \, dm = \frac{2}{3} E_{\text{int}} \), where \( E_{\text{int}} \) is the total internal energy of the star. The virial theorem for an ideal gas is therefore

\[ E_{\text{int}} = -\frac{1}{2} E_{\text{gr}}. \]  

(2.27)

This important relation establishes a link between the gravitational potential energy and the internal energy of a star in hydrostatic equilibrium that consists of an ideal gas. (We shall see later that the ideal gas law indeed holds for most stars, at least on the main sequence.) The virial theorem tells us that a more tightly bound star must have a higher internal energy, i.e. it must be hotter. In other words, a star that contracts quasi-statically must get hotter in the process. The full implications of this result will become clear when we consider the total energy of a star in a short while.
**Estimate of the central temperature** Using the virial theorem we can obtain an estimate of the average temperature inside a star composed of ideal gas. The gravitational energy of the star is found from eq. (2.20) and can be written as

\[ E_{gr} = -\alpha \frac{GM^2}{R}, \]  

(2.28)

where \( \alpha \) is a constant of order unity (determined by the distribution of matter in the star, i.e. by the density profile). Using eq. (2.26), the internal energy of the star is \( E_{int} = \frac{3}{2} k / (\mu m_u) \int T dm = \frac{3}{2} k / (\mu m_u) \bar{T} M \), where \( \bar{T} \) is the temperature averaged over all mass shells. By the virial theorem we then obtain

\[ \bar{T} = \frac{\alpha \mu m_u GM}{3 k R}. \]  

(2.29)

Taking \( \alpha \approx 1 \) and \( \mu = 0.5 \) for ionized hydrogen, we obtain for the Sun \( \bar{T} \sim 4 \times 10^6 \) K. This is the average temperature required to provide the pressure that is needed to keep the Sun in hydrostatic equilibrium. Since the temperature in a star normally decreases outwards, it is also an approximate lower limit on the central temperature of the Sun. At these temperatures, hydrogen and helium are indeed completely ionized. We shall see that \( T_c \approx 10^7 \) K is high enough for hydrogen fusion to take place in the central regions of the Sun.

**The virial theorem for a general equation of state** Also for equations of state other than an ideal gas a relation between pressure and internal energy exists, which we can write generally as

\[ u = \phi \frac{P}{\rho}. \]  

(2.30)

We have seen above that \( \phi = \frac{3}{2} \) for an ideal gas, but it will turn out (see Ch. 3) that this is valid not only for an ideal gas, but for all non-relativistic particles. On the other hand, if we consider a gas of relativistic particles, in particular photons (i.e. radiation pressure), \( \phi = 3 \). If \( \phi \) is constant throughout the star we can integrate the left-hand side of eq. (2.23) to obtain a more general form of the virial theorem:

\[ E_{int} = -\frac{1}{\phi} E_{gr} \]  

(2.31)

**2.3.1 The total energy of a star**

The total energy of a star is the sum of its gravitational potential energy, its internal energy and its kinetic energy \( E_{kin} \) (due to bulk motions of gas inside the star, not the thermal motions of the gas particles):

\[ E_{tot} = E_{gr} + E_{int} + E_{kin}. \]  

(2.32)

The star is bound as long as its total energy is negative. For a star in hydrostatic equilibrium we can set \( E_{kin} = 0 \). Furthermore for a star in HE the virial theorem holds, so that \( E_{gr} \) and \( E_{int} \) are tightly related by eq. (2.31). Combining eqs. (2.31) and (2.32) we obtain the following relations:

\[ E_{tot} = E_{int} + E_{gr} = \frac{\phi - 3}{\phi} E_{int} = (1 - \frac{1}{3} \phi) E_{gr} \]  

(2.33)
As long as $\phi < 3$ the star is bound. This is true in particular for the important case of a star consisting of an ideal gas (eq. 2.27), for which we obtain

$$ E_{\text{tot}} = E_{\text{int}} + E_{\text{gr}} = -E_{\text{int}} = \frac{1}{2}E_{\text{gr}} < 0 \quad (2.34) $$

In other words, its total energy of such a star equals half of its gravitational potential energy.

From eq. (2.34) we can see that the virial theorem has the following important consequences:

- Gravitationally bound gas spheres must be hot to maintain hydrostatic equilibrium: heat provides the pressure required to balance gravity. The more compact such a sphere, the more strongly bound, and therefore the hotter it must be.

- A hot sphere of gas radiates into surrounding space, therefore a star must lose energy from its surface. The rate at which energy is radiated from the surface is the luminosity of the star. In the absence of an internal energy source, this energy loss must equal the decrease of the total energy of the star: $L = -dE_{\text{int}}/dt > 0$, since $L$ is positive by convention.

- Taking the time derivative of eq. (2.34), we find that as a consequence of losing energy:

$$ \dot{E}_{\text{gr}} = -2L < 0, $$

meaning that the star contracts (becomes more strongly bound), and

$$ \dot{E}_{\text{int}} = L > 0, $$

meaning that the star gets hotter – unlike familiar objects which cool when they lose energy. Therefore a star can be said to have a negative heat capacity. Half the energy liberated by contraction is used for heating the star, the other half is radiated away.

For the case of a star that is dominated by radiation pressure, we find that $E_{\text{int}} = -E_{\text{gr}}$, and therefore the total energy $E_{\text{tot}} = 0$. Therefore a star dominated by radiation pressure (or more generally, by the pressure of relativistic particles) is only marginally bound. No energy is required to expand or contract such a star, and a small perturbation would be enough to render it unstable and to trigger its collapse or complete dispersion.

### 2.3.2 Thermal equilibrium

If internal energy sources are present in a star due to nuclear reactions taking place in the interior, then the energy loss from the surface can be compensated: $L = L_{\text{nuc}} \equiv -dE_{\text{nuc}}/dt$. In that case the total energy is conserved and eq. (2.34) tells us that $\dot{E}_{\text{tot}} = \dot{E}_{\text{int}} = \dot{E}_{\text{gr}} = 0$. The virial theorem therefore states that both $E_{\text{int}}$ and $E_{\text{gr}}$ are conserved as well: the star cannot, for example, contract and cool while keeping its total energy constant.

In this state, known as thermal equilibrium (TE), the star is in a stationary state. Energy is radiated away at the surface at the same rate at which it is produced by nuclear reactions in the interior. The star neither expands nor contracts, and it maintains a constant interior temperature. We shall see later that this temperature is regulated by the nuclear reactions themselves, which in combination with the virial theorem act like a stellar thermostat. Main-sequence stars like the Sun are in thermal equilibrium, and a star can remain in this state as long as nuclear reactions can supply the necessary energy.
Note that the arguments given above imply that both hydrostatic equilibrium and thermal equilibrium are stable equilibria, an assumption that we have yet to prove (see Ch. 7). It is relatively easy to understand why TE is stable, at least as long as the ideal-gas pressure dominates ($\phi < 3$ in eq. 2.31). Consider what happens when TE is disturbed, e.g. when $L_{\text{nuc}} > L$ temporarily. The total energy then increases, and the virial theorem states that as a consequence the star must expand and cool. Since the nuclear reaction rates typically increase strongly with temperature, the rate of nuclear burning and thus $L_{\text{nuc}}$ will decrease as a result of this cooling, until TE is restored when $L = L_{\text{nuc}}$.

2.4 The timescales of stellar evolution

Three important timescales are relevant for stellar evolution, associated with changes to the mechanical structure of a star (described by the equation of motion, eq. 2.11), changes to its thermal structure (as follows from the virial theorem, see also Sect. 5.1) and changes in its composition, which will be discussed in Ch. 6.

The first timescale was already treated in Sec. 2.2.1: it is the dynamical timescale given by eq. (2.18),

$$\tau_{\text{dyn}} \approx \left( \frac{R^3}{GM} \right)^{1/2} \approx 0.02 \left( \frac{R}{R_{\odot}} \right)^{3/2} \left( \frac{M}{M_{\odot}} \right)^{1/2} \text{ days}$$

The dynamical timescale is the timescale on which a star reacts to a perturbation of hydrostatic equilibrium. We saw that this timescale is typically of the order of hours or less, which means that stars are extremely close to hydrostatic equilibrium.

2.4.1 The thermal timescale

The second timescale describes how fast changes in the thermal structure of a star can occur. It is therefore also the timescale on which a star in thermal equilibrium reacts when its TE is perturbed. To obtain an estimate, we turn to the virial theorem: we saw in Sec. 2.3.1 that a star without a nuclear energy source contracts by radiating away its internal energy content: $L = E_{\text{int}} \approx -2E_{\text{gr}}$, where the last equality applies strictly only for an ideal gas. We can thus define the thermal or Kelvin-Helmholtz timescale as the timescale on which this gravitational contraction would occur:

$$\tau_{\text{KH}} = \frac{E_{\text{int}}}{L} \approx \frac{|E_{\text{gr}}|}{2L} \approx \frac{GM^2}{2RL} \approx 1.5 \times 10^7 \left( \frac{M}{M_{\odot}} \right)^2 \frac{R_{\odot} L_{\odot}}{R L} \text{ yr}$$

Here we have used eq. (2.28) for $E_{\text{gr}}$ with $\alpha \approx 1$.

The thermal timescale for the Sun is about $1.5 \times 10^7$ years, which is many orders of magnitude larger than the dynamical timescale. There is therefore no direct observational evidence that any star is in thermal equilibrium. In the late 19th century gravitational contraction was proposed as the energy source of the Sun by Lord Kelvin and, independently, by Hermann von Helmholtz. This led to an age of the Sun and an upper limit to the age the Earth that was in conflict with emerging geological evidence, which required the Earth to be much older. Nuclear reactions have since turned out to be a much more powerful energy source than gravitational contraction, allowing stars to be in thermal equilibrium for most ($> 99\%$) of their lifetimes. However, several phases of stellar evolution, during which the nuclear power source is absent or inefficient, do occur on the thermal timescale.
2.4.2 The nuclear timescale

A star can remain in thermal equilibrium for as long as its nuclear fuel supply lasts. The associated timescale is called the nuclear timescale, and since nuclear fuel (say hydrogen) is burned into ‘ash’ (say helium), it is also the timescale on which composition changes in the stellar interior occur.

The energy source of nuclear fusion is the direct conversion of a small fraction $\phi$ of the rest mass of the reacting nuclei into energy. For hydrogen fusion, $\phi \approx 0.007$; for fusion of helium and heavier elements $\phi$ is smaller by a factor 10 or more. The total nuclear energy supply can therefore be written as $E_{\text{nuc}} = \phi M_{\text{nuc}} c^2 = \phi f_{\text{nuc}} M c^2$, where $f_{\text{nuc}}$ is that fraction of the mass of the star which may serve as nuclear fuel. In thermal equilibrium $L = L_{\text{nuc}} = \dot{E}_{\text{nuc}}$, so we can estimate the nuclear timescale as

$$\tau_{\text{nuc}} = \frac{E_{\text{nuc}}}{L} = \phi f_{\text{nuc}} \frac{M c^2}{L} \approx 10^{10} \frac{M}{M_\odot} \frac{L}{L_\odot} \text{yr.} \quad (2.37)$$

The last approximate equality holds for hydrogen fusion in a star like the Sun, with has 70% of its initial mass in hydrogen and fusion occurring only in the inner $\approx 10\%$ of its mass (the latter result comes from detailed stellar models). This long timescale is consistent with the geological evidence for the age of the Earth.

We see that, despite only a small fraction of the mass being available for fusion, the nuclear timescale is indeed two to three orders of magnitude larger than the thermal timescale. Therefore the assumption that stars can reach a state of thermal equilibrium is justified. To summarize, we have found:

$$\tau_{\text{nuc}} \gg \tau_{\text{KH}} \gg \tau_{\text{dyn}}.$$ 

As a consequence, the rates of nuclear reactions determine the pace of stellar evolution, and stars may be assumed to be in hydrostatic and thermal equilibrium throughout most of their lives.

Suggestions for further reading

The contents of this chapter are covered more extensively by Chapter 1 of Maeder and by Chapters 1 to 4 of Kippenhahn & Weigert.

Exercises

2.1 Density profile

In a star with mass $M$, assume that the density decreases from the center to the surface as a function of radial distance $r$, according to

$$\rho = \rho_c \left[ 1 - \left( \frac{r}{R} \right)^2 \right]. \quad (2.38)$$

where $\rho_c$ is a given constant and $R$ is the radius of the star.

(a) Find $m(r)$.

(b) Derive the relation between $M$ and $R$.

(c) Show that the average density of the star is $0.4\rho_c$. 

18
2.2 Hydrostatic equilibrium

(a) Consider an infinitesimal mass element \( dm \) inside a star, see Fig. 2.1. What forces act on this mass element?

(b) Newton’s second law of mechanics, or the equation of motion, states that the net force acting on a body is equal to its acceleration times its mass. Write down the equation of motion for the gas element.

(c) In hydrostatic equilibrium the net force is zero and the gas element is not accelerated. Find an expression of the pressure gradient in hydrostatic equilibrium.

(d) Find an expression for the central pressure \( P_c \) by integrating the pressure gradient. Use this to derive the lower limit on the central pressure of a star in hydrostatic equilibrium, eq. (2.16).

(e) Verify the validity of this lower limit for the case of a star with the density profile of eq. (2.38).

2.3 The virial theorem

An important consequence of hydrostatic equilibrium is that it links the gravitational potential energy \( E_{gr} \) and the internal thermal energy \( E_{int} \).

(a) Estimate the gravitational energy \( E_{gr} \) for a star with mass \( M \) and radius \( R \), assuming (1) a constant density distribution and (2) the density distribution of eq. (2.38).

(b) Assume that a star is made of an ideal gas. What is the kinetic internal energy per particle for an ideal gas? Show that the total internal energy, \( E_{int} \) is given by:

\[
E_{int} = \int_0^R \left( \frac{3}{2} \frac{k}{\mu m_u} \rho \langle T \rangle \right) \frac{4}{3} \pi r^2 dr.
\]

(c) Estimate the internal energy of the Sun by assuming constant density and \( T(r) \approx \langle T \rangle \approx \frac{1}{4} T_c \approx 5 \times 10^8 \text{K} \) and compare your answer to your answer for a). What is the total energy of the Sun? Is the Sun bound according to your estimates?

It is no coincidence that the order of magnitude for \( E_{gr} \) and \( E_{int} \) are the same\(^1\). This follows from hydrostatic equilibrium and the relation is known as the virial theorem. In the next steps we will derive the virial theorem starting from the pressure gradient in the form of eq. (2.12).

(d) Multiply by both sides of eq. (2.12) by \( 4\pi r^3 \) and integrate over the whole star. Use integration by parts to show that

\[
\int_0^R 3 P \frac{4}{3} \pi r^2 dr = \int_0^R Gm(r) \rho \frac{4}{3} \pi r^2 dr.
\]

(e) Now derive a relation between \( E_{gr} \) and \( E_{int} \), the virial theorem for an ideal gas.

(f) (*) Also show that for the average pressure of the star

\[
\langle P \rangle = \frac{1}{V} \int_0^R P \frac{4}{3} \pi r^2 dr = -\frac{1}{3} \frac{E_{gr}}{V},
\]

where \( V \) is the volume of the star.

As the Sun evolved towards the main sequence, it contracted under gravity while remaining close to hydrostatic equilibrium. Its internal temperature changed from about 30 000 K to about \( 6 \times 10^8 \text{K} \).

(g) Find the total energy radiated during away this contraction. Assume that the luminosity during this contraction is comparable to \( L_\odot \) and estimate the time taken to reach the main sequence.

2.4 Conceptual questions

\(^1\)In reality \( E_{gr} \) is larger than estimated above because the mass distribution is more concentrated to the centre.
(a) Use the virial theorem to explain why stars are hot, i.e. have a high internal temperature and therefore radiate energy.

(b) What are the consequences of energy loss for the star, especially for its temperature?

(c) Most stars are in thermal equilibrium. What is compensating for the energy loss?

(d) What happens to a star in thermal equilibrium (and in hydrostatic equilibrium) if the energy production by nuclear reactions in a star drops (slowly enough to maintain hydrostatic equilibrium)?

(e) Why does this have a stabilizing effect? On what time scale does the change take place?

(f) What happens if hydrostatic equilibrium is violated, e.g. by a sudden increase of the pressure.

(g) On which timescale does the change take place? Can you give examples of processes in stars that take place on this timescale.

2.5 Three important timescales in stellar evolution

(a) The nuclear timescale \( \tau_{\text{nuc}} \).

i. Calculate the total mass of hydrogen available for fusion over the lifetime of the Sun, if 70% of its mass was hydrogen when the Sun was formed, and only 13% of all hydrogen is in the layers where the temperature is high enough for fusion.

ii. Calculate the fractional amount of mass converted into energy by hydrogen fusion. (Refer to Table 1 for the mass of a proton and of a helium nucleus.)

iii. Derive an expression for the nuclear timescale in solar units, i.e. expressed in terms of \( R/R_\odot \), \( M/M_\odot \) and \( L/L_\odot \).

iv. Use the mass-radius and mass-luminosity relations for main-sequence stars to express the nuclear timescale of main-sequence stars as a function of the mass of the star only.

v. Describe in your own words the meaning of the nuclear timescale.

(b) The thermal timescale \( \tau_{\text{KH}} \).

i-iii. Answer question (a) iii, iv and v for the thermal timescale and calculate the age of the Sun according to Kelvin.

iv. Why are most stars observed to be main-sequence stars and why is the Hertzsprung-gap called a gap?

(c) The dynamical timescale \( \tau_{\text{dyn}} \).

i-iii. Answer question (a) iii, iv and v for the dynamical timescale.

iv. In stellar evolution models one often assumes that stars evolve quasi-statically, i.e. that the star remains in hydrostatic equilibrium throughout. Why can we make this assumption?

v. Rapid changes that are sometimes observed in stars may indicate that dynamical processes are taking place. From the timescales of such changes - usually oscillations with a characteristic period - we may roughly estimate the average density of the star. The sun has been observed to oscillate with a period of minutes, white dwarfs with periods of a few tens of seconds. Estimate the average density for the Sun and for white dwarfs.

(d) Comparison.

i. Summarize your results for the questions above by computing the nuclear, thermal and dynamical timescales for a 1, 10 and 25 \( M_\odot \) main-sequence star. Put your answers in tabular form.

ii. For each of the following evolutionary stages indicate on which timescale they occur: pre-main sequence contraction, supernova explosion, core hydrogen burning, core helium burning.

iii. When the Sun becomes a red giant (RG), its radius will increase to 200\( R_\odot \) and its luminosity to 3000\( L_\odot \). Estimate \( \tau_{\text{dyn}} \) and \( \tau_{\text{KH}} \) for such a RG.

iv. How large would such a RG have to become for \( \tau_{\text{dyn}} > \tau_{\text{KH}} \)? Assume both R and L increase at constant effective temperature.
Chapter 3

Equation of state of stellar interiors

3.1 Local thermodynamic equilibrium

Empirical evidence shows that in a part of space isolated from the rest of the Universe, matter and radiation tend towards a state of *thermodynamic equilibrium*. This equilibrium state is achieved when sufficient interactions take place between the material particles (‘collisions’) and between the photons and mass particles (scatterings and absorptions). In such a state of thermodynamic equilibrium the radiation field becomes isotropic and the photon energy distribution is described by the Planck function (blackbody radiation). The statistical distribution functions of both the mass particles and the photons are then characterized by a single temperature \( T \).

We know that stars are not isolated systems, because they emit radiation and generate (nuclear) energy in their interiors. Indeed, the surface temperature of the Sun is about 6000 K, while we have estimated from the virial theorem (Sec. 2.3) that the interior temperature must of the order of \( 10^7 \) K. Therefore stars are *not* in global thermodynamic equilibrium. However, it turns out that locally within a star, a state of thermodynamic equilibrium *is* achieved. This means that within a region much smaller than the dimensions of a star (\( \ll R_* \)), but larger than the average distance between interactions of the particles (both gas particles and photons), i.e. larger than the mean free path, there is a well-defined local temperature that describes the particle statistical distributions.

We can make this plausible by considering the mean free path for photons:

\[ \ell_{\text{ph}} = \frac{1}{\kappa \rho} \]

where \( \kappa \) is the opacity coefficient, i.e. the effective cross section per unit mass. For fully ionized matter, a minimum is given by the electron scattering cross section, which is \( \kappa_{\text{es}} = 0.4 \text{ cm}^2/\text{g} \) (see Ch. 5). The average density in the Sun is \( \bar{\rho} = 1.4 \text{ g/cm}^3 \), which gives a mean free path of the order of \( \ell_{\text{ph}} \sim 1 \text{ cm} \). In other words, stellar matter is very opaque to radiation. The temperature difference over a distance \( \ell_{\text{ph}} \), i.e. between emission and absorption, can be estimated as

\[ \Delta T \approx \frac{dT}{dr} \ell_{\text{ph}} \approx \frac{T_e}{R} \ell_{\text{ph}} \approx \frac{10^7}{10^{11}} \approx 10^{-4} \text{ K} \]

which is a tiny fraction (\( 10^{-11} \)) of the typical interior temperature of \( 10^7 \) K. Using a similar estimate, it can be shown that the mean free path for interactions between ionized gas particles (ions and electrons) is several orders of magnitude smaller than \( \ell_{\text{ph}} \). Hence a small region can be defined (a ‘point’ for all practical purposes) which is \( > \ell_{\text{ph}} \) but much smaller than the length scale over which significant changes of thermodynamic quantities occur. This is called *local thermodynamic equilibrium* (LTE). We can therefore assume a well-defined temperature distribution inside the star.
Furthermore, the average time between particle interactions (the mean free time) is much shorter than the timescale for changes of the macroscopic properties. Therefore a state of LTE is secured at all times in the stellar interior. The assumption of LTE\(^1\) constitutes a great simplification. It enables the calculation of all thermodynamic properties of the stellar gas in terms of the local values of temperature, density and composition, as they change from the centre to the surface.

### 3.2 The equation of state

The equation of state (EOS) describes the microscopic properties of stellar matter, for given density $\rho$, temperature $T$ and composition $X_i$. It is usually expressed as the relation between the pressure and these quantities:

$$ P = P(\rho, T, X_i) \quad (3.1) $$

Using the laws of thermodynamics, and a similar equation for the internal energy $U(\rho, T, X_i)$, we can derive from the EOS the thermodynamic properties that are needed to describe the structure of a star, such as the specific heats $c_V$ and $c_P$, the adiabatic exponent $\gamma_{ad}$ and the adiabatic temperature gradient $\nabla_{ad}$.

An example is the ideal-gas equation of state, which in the previous chapters we have tacitly assumed to hold for stars like the Sun:

$$ P = nkT \quad \text{or} \quad P = \frac{k}{\mu m_u} \rho T. $$

In this chapter we will see whether this assumption was justified, and how the EOS can be extended to cover all physical conditions that may prevail inside a star. The ideal-gas law pertains to particles that behave according to classical physics. However, both quantum-mechanical and special relativistic effects may be important under the extreme physical conditions in stellar interiors. In addition, photons (which can be described as extremely relativistic particles) can be an important source of pressure.

We can define an ideal or perfect gas as a mixture of free, non-interacting particles. Of course the particles in such a gas do interact, so more precisely we require that their interaction energies are small compared to their kinetic energies. In that case the internal energy of the gas is just the sum of all kinetic energies. From statistical mechanics we can derive the properties of such a perfect gas, both in the classical limit (recovering the ideal-gas law) and in the quantum-mechanical limit (leading to electron degeneracy), and both in the non-relativistic and in the relativistic limit (e.g. valid for radiation). This is done in Sect. 3.3.

In addition, various non-ideal effects may become important. The high temperatures ($> 10^6$ K) in stellar interiors ensure that the gas will be fully ionized, but at lower temperatures (in the outer layers) partial ionization has to be considered, with important effects on the thermodynamic properties (see Sect. 3.5). Furthermore, in an ionized gas electrostatic interactions between the ions and electrons may be important under certain circumstances (Sect. 3.6).

### 3.3 Equation of state for a gas of free particles

We shall derive the equation of state for a perfect gas from the principles of statistical mechanics. This provides a description of the ions, the electrons, as well as the photons in the deep stellar interior.

---

\(^1\)N.B. note the difference between (local) thermodynamic equilibrium ($T_{\text{gas}}(r) = T_{\text{rad}}(r) = T(r)$) and the earlier defined, global property of thermal equilibrium ($E_{\text{tot}} = \text{const}$, or $L = L_{\text{nuc}}$).
Let $n(p)$ be the distribution of momenta of the gas particles, i.e. $n(p)\, dp$ represents the number of particles per unit volume with momenta $p \in [p \ldots p + dp]$. If $n(p)$ is known then the total number density (number of particles per unit volume), the internal energy density (internal energy per unit volume) and the pressure can be obtained from the following integrals:

\[
\text{number density} \quad n = \int_0^\infty n(p) \, dp \quad (3.2)
\]

\[
\text{internal energy density} \quad U = \int_0^\infty \epsilon_p n(p) \, dp = n(\epsilon_p) \quad (3.3)
\]

\[
\text{pressure} \quad P = \frac{1}{3} \int_0^\infty p v_p n(p) \, dp = \frac{1}{3} n(p v_p) \quad (3.4)
\]

Here $\epsilon_p$ is the kinetic energy of a particle with momentum $p$, and $v_p$ is its velocity. Eq. (3.2) is trivial, and eq. (3.3) follows from the perfect-gas assumption. The pressure integral eq. (3.4) requires some explanation.

Consider a gas of $n$ particles in a cubical box with sides of length $L = 1$ cm. Each particle bounces around in the box, and the pressure on one side of the box results from the momentum imparted by all the particles colliding with it. Consider a particle with momentum $p$ and corresponding velocity $v$ coming in at an angle $\theta$ with the normal to the surface, as depicted in Fig. 3.1. The time between two collisions with the same side is

\[
\Delta t = \frac{2L}{v \cos \theta} = \frac{2}{v \cos \theta}.
\]

The collisions are elastic, so the momentum transfer is twice the momentum component perpendicular to the surface,

\[
\Delta p = 2p \cos \theta. \quad (3.5)
\]

The momentum transferred per particle per second and per cm$^2$ is therefore

\[
\frac{\Delta p}{\Delta t} = v p \cos^2 \theta. \quad (3.6)
\]

The number of particles in the box with $p \in [p \ldots p + dp]$ and $\theta \in [\theta \ldots \theta + d\theta]$ is denoted as $n(\theta, p)\, d\theta\, dp$. The contribution to the pressure from these particles is then

\[
dP = v p \cos^2 \theta n(\theta, p)\, d\theta\, dp. \quad (3.7)
\]

\[\text{Figure 3.1.} \quad \text{Gas particle in a cubical box with a volume of 1 cm}^3. \text{ Each collision with the side of the box results in a transfer of momentum; the pressure inside the box is the result of the collective momentum transfers of all n particles in the box.}\]
Since the momenta are distributed isotropically over all directions within a solid angle $2\pi$, and the solid angle $d\omega$ subtended by those particles with $\theta \in [\theta \ldots \theta + d\theta]$ equals $2\pi \sin \theta d\theta$, we have $n(\theta, p) d\theta = n(p) \sin \theta d\theta$ and

$$dP = vp n(p) \cos^2 \theta \sin \theta d\theta dp.$$  \hspace{1cm} (3.8)

The total pressure is obtained by integrating over all angles ($0 \leq \theta \leq \pi/2$) and momenta. This results in eq. (3.4) since $\int_0^{\pi/2} \cos^2 \theta \sin \theta d\theta = \int_0^1 \cos^2 \theta d\cos \theta = \frac{1}{2}$.

### 3.3.1 Relation between pressure and internal energy

In general, the particle energies and velocities are related to their momenta according to special relativity:

$$\epsilon^2 = p^2 c^2 + m^2 c^4, \quad \epsilon_p = \epsilon - mc^2$$ \hspace{1cm} (3.9)

and

$$v_p = \frac{\partial \epsilon}{\partial p} = \frac{pc^2}{\epsilon}.$$ \hspace{1cm} (3.10)

We can obtain generally valid relations between the pressure and the internal energy of a perfect gas in the non-relativistic (NR) limit and the extremely relativistic (ER) limit:

**NR limit:** in this case the momenta $p \ll mc$, so that $\epsilon_p = \epsilon - mc^2 = \frac{1}{2}p^2/m$ and $v = p/m$. Therefore $\langle pv \rangle = \langle p^2/m \rangle = 2\langle \epsilon_p \rangle$ so that eq. (3.4) yields

$$P = \frac{2}{3}U$$ \hspace{1cm} (3.11)

**ER limit:** in this case $p \gg mc$, so that $\epsilon_p = pc$ and $v = c$. Therefore $\langle pv \rangle = \langle pc \rangle = \langle \epsilon_p \rangle$, and eq. (3.4) yields

$$P = \frac{1}{3}U$$ \hspace{1cm} (3.12)

These relations are generally true, for any particle (electrons, ions and photons). We will apply this in the coming sections. As we saw in the previous Chapter, the change from $\frac{2}{3}$ to $\frac{1}{3}$ in the relation has important consequences for the virial theorem, and for the stability of stars.

### 3.3.2 The classical ideal gas

Using the tools of statistical mechanics, we can address the origin of the ideal-gas law. The momentum distribution $n(p)$ for classical, non-relativistic particles of mass $m$ in LTE is given by the Maxwell-Boltzmann distribution:

$$n(p) dp = \frac{n}{(2\pi mkT)^{3/2}} e^{-p^2/2mkT} 4\pi p^2 dp.$$ \hspace{1cm} (3.13)

Here the exponential factor ($e^{-\epsilon_p/kT}$) represents the equilibrium distribution of kinetic energies, the factor $4\pi p^2 dp$ is the volume in momentum space ($p_x, p_y, p_z$) for $p \in [p \ldots p + dp]$, and the factor $n/(2\pi mkT)^{3/2}$ comes from the normalization of the total number density $n$ imposed by eq. (3.2). (You can verify this by starting from the standard integral $\int_0^\infty e^{-ax^2} dx = \frac{1}{2} \sqrt{\pi/a}$, and differentiating once with respect to $a$ to obtain the integral $\int_0^\infty x^2 e^{-ax^2} dx.$)
The pressure is calculated by using \( v = p/m \) for the velocity in eq. (3.4):

\[
P = \frac{1}{3n} \left( \frac{2\pi mkT}{n} \right)^{3/2} \int_0^{\infty} \frac{P^2}{m} e^{-p^2/(2mkT)} 4\pi p^2 \, dp.
\]  

(3.14)

By performing the integration (for this you need to differentiate \( \int_0^{\infty} e^{-ax} x^2 \, dx \) once more with respect to \( a \)) you can verify that this indeed yields the ideal gas law

\[
P = nkT.
\]  

(3.15)

(N.B. This derivation is for a gas of non-relativistic classical particles, but it can be shown that the same relation \( P = nkT \) is also valid for relativistic classical particles.)

### 3.3.3 Mixture of ideal gases, and the mean molecular weight

The ideal gas relation was derived for identical particles of mass \( m \). It should be obvious that for a mixture of free particles of different species, it holds for the partial pressures of each of the constituents of the gas separately. In particular, it holds for both the ions and the electrons, as long as quantum-mechanical effects can be ignored. The total gas pressure is then just the sum of partial pressures

\[
P_{\text{gas}} = P_{\text{ion}} + P_e = \sum_i P_i + P_e = (\sum_i n_i + n_e)kT = nkT
\]

where \( n_i \) is the number density of ions of element \( i \), with mass \( m_i = A_i m_u \) and charge \( Z_i e \). Then \( n_i \) is related to the density and the mass fraction \( X_i \) of this element as

\[
n_i = \frac{X_i \rho}{A_i m_u} \quad \text{and} \quad n_{\text{ion}} = \sum_i \frac{X_i \rho}{A_i m_u} = \frac{1}{\mu_{\text{ion}} m_u},
\]

(3.16)

which defines the mean atomic mass per ion \( \mu_{\text{ion}} \). The partial pressure due to all ions is then

\[
P_{\text{ion}} = \frac{1}{\mu_{\text{ion}} m_u} kT = \frac{R}{\mu_{\text{ion}}} \rho T.
\]

(3.17)

We have used here the universal gas constant \( R = k/m_u = 8.31447 \times 10^7 \) erg g\(^{-1}\) K\(^{-1}\). The number density of electrons is given by

\[
n_e = \sum_i Z_i n_i = \sum_i \frac{Z_i X_i \rho}{A_i m_u} = \frac{1}{\mu_e m_u},
\]

(3.18)

which defines the mean molecular weight per free electron \( \mu_e \). As long as the electrons behave like classical particles, the electron pressure is thus given by

\[
P_e = \frac{1}{\mu_e m_u} kT = \frac{R}{\mu_e} \rho T.
\]

(3.19)

When the gas is fully ionized, we have for hydrogen \( Z_i = A_i = 1 \) while for helium and the most abundant heavier elements, \( Z_i/A_i \approx \frac{1}{2} \). In terms of the hydrogen mass fraction \( X \) we then get

\[
\mu_e \approx \frac{2}{1 + X},
\]

(3.20)

which for the Sun (\( X = 0.7 \)) amounts to \( \mu_e \approx 1.18 \), and for hydrogen-depleted gas gives \( \mu_e \approx 2 \).

The total gas pressure is then given by

\[
P_{\text{gas}} = P_{\text{ion}} + P_e = \left( \frac{1}{\mu_{\text{ion}}} + \frac{1}{\mu_e} \right) R \rho T = \frac{R}{\mu} \rho T
\]

(3.21)
where the mean molecular weight $\mu$ is given by
\[
\frac{1}{\mu} = \frac{1}{\mu_{\text{ion}}} + \frac{1}{\mu_e} = \sum_i \frac{(Z_i + 1)X_i}{A_i}.
\tag{3.22}
\]

It is left as an exercise to show that for a fully ionized gas, $\mu$ can be expressed in terms of the mass fractions $X$, $Y$ and $Z$ as
\[
\mu \approx \frac{1}{2X + \frac{3}{2}Y + \frac{1}{2}Z}
\tag{3.23}
\]
if we assume that for elements heavier than helium, $A_i \approx 2Z_i \approx 2(Z_i + 1)$.

### 3.3.4 Quantum-mechanical description of the gas

According to quantum mechanics, the accuracy with which a particle’s location and momentum can be known simultaneously is limited by Heisenberg’s uncertainty principle, i.e. $\Delta x \Delta p \geq h$. In three dimensions, this means that if a particle is located within a volume element $\Delta V$ then its localization within three-dimensional momentum space $\Delta^3 p$ is constrained by
\[
\Delta V \Delta^3 p \geq h^3.
\tag{3.24}
\]
The quantity $h^3$ defines the volume in six-dimensional phase space of one quantum cell. The number of quantum states in a spatial volume $V$ and with momenta $p \in [p \ldots p + dp]$ is therefore given by
\[
g(p) \, dp = g_s \frac{V}{h^3} \frac{4\pi p^2}{\hbar^3} \, dp,
\tag{3.25}
\]
where $g_s$ is the number of intrinsic quantum states of the particle, e.g. spin or polarization.

The relative occupation of the available quantum states for particles in thermodynamic equilibrium depends on the type of particle:

- **fermions** (e.g. electrons or nucleons) obey the Pauli exclusion principle, which postulates that no two such particles can occupy the same quantum state. The fraction of states with energy $\epsilon_p$ that will be occupied at temperature $T$ is given by
  \[
f_{\text{FD}}(\epsilon_p) = \frac{1}{e^{(\epsilon_p - \mu)/kT} + 1},
\tag{3.26}
\]
  which is always $\leq 1$.

- **bosons** (e.g. photons) have no restriction on the number of particles per quantum state, and the fraction of states with energy $\epsilon_p$ that is occupied is
  \[
f_{\text{BE}}(\epsilon_p) = \frac{1}{e^{(\epsilon_p - \mu)/kT} - 1},
\tag{3.27}
\]
  which can be $> 1$.

The actual distribution of momenta for particles in LTE is given by the product of the occupation fraction $f(\epsilon_p)$ and the number of quantum states, given by eq. (3.25). The quantity $\mu$ appearing in eqs. (3.26) and (3.27) is the so-called chemical potential. It can be seen as a normalization constant, determined by the total number of particles in the volume considered (i.e., by the constraint imposed by eq. 3.2).
Electrons are fermions with two spin states, i.e. \( g_e = 2 \). According to eq. (3.25), the maximum number density of electrons with momentum \( p \) allowed by quantum mechanics is therefore

\[
n_{\text{max}}(p) \, dp = \frac{g_e}{h^3} \frac{4\pi p^2}{dp} = \frac{8\pi}{h^3} p^2 \, dp.
\] (3.28)

This is shown as the dotted line in Fig. 3.2. The actual momentum distribution of electrons \( n_e(p) \) is given by the product of eq. (3.28) and eq. (3.26). In the non-relativistic limit we have \( \epsilon_p = p^2/2m_e \), giving

\[
n_e(p) \, dp = \frac{2}{h^3} \frac{1}{e^{(p^2/2m_e kT)} - 1} 4\pi p^2 \, dp,
\] (3.29)

where we have replaced the chemical potential by the degeneracy parameter \( \psi = \mu/kT \). The value of \( \psi \) is determined by the constraint that \( \int_0^{\infty} n_e(p) \, dp = n_e \) (eq. 3.2).

The limitation imposed by the Pauli exclusion principle means that electrons can exert a higher pressure than predicted by classical physics (eq. 3.19). To illustrate this, in Fig. 3.2 the momentum distribution eq. (3.29) is compared to the Maxwell-Boltzmann distribution for electrons, eq. (3.13),

\[
n_{\text{MB}}(p) \, dp = \frac{n_e}{(2\pi m_e kT)^{3/2}} e^{-p^2/2m_e kT} 4\pi p^2 \, dp.
\] (3.30)

The situation shown is for an electron density \( n_e = 6 \times 10^{27} \text{ cm}^{-3} \), which corresponds to a mass density of \( 2 \times 10^4 \text{ g/cm}^{-3} \) (assuming a hydrogen-depleted gas with \( \mu_e = 2 \)). At high temperatures, \( T = 2 \times 10^7 \text{ K} \), the momentum distribution (solid line) nearly coincides with the M-B distribution.
(dashed line): none of the quantum states are fully occupied ($n_e(p) < n_{\text{max}}(p)$ for all values of $p$) and the electrons behave like classical particles. As the temperature is decreased, e.g. at $T = 2 \times 10^6$ K (red lines), the peak in the M-B distribution shifts to smaller $p$ and is higher (since the integral over the distribution must equal $n_e$). The number of electrons with small values of $p$ exceeds the maximum allowed by the Pauli exclusion principle, $n_{\text{max}}(p)$. These electrons are forced to assume quantum states with higher $p$: the peak in the distribution $n_e(p)$ occurs at higher $p$. Due to the higher momenta and velocities of these electrons, the electron gas exerts a higher pressure than inferred from classical physics. This is called degeneracy pressure. If the temperature is decreased even more, e.g. at $T = 2 \times 10^5$ K (blue lines), the lowest momentum states become nearly all filled and $n_e(p)$ follows $n_{\text{max}}(p)$ until it drops sharply. In this state of strong degeneracy, further decrease of $T$ hardly changes the momentum distribution, so that the electron pressure becomes nearly independent of temperature.

**Complete electron degeneracy**

In the limit that $T \to 0$, all available momentum states are occupied up to a maximum value, while all higher states are empty, as illustrated in the right panel of Fig. 3.2. This is known as complete degeneracy, and the maximum momentum is called the *Fermi momentum* $p_F$. Then we have

$$n_e(p) = \frac{8\pi p^2}{h^3} \quad \text{for } p \leq p_F, \quad (3.31)$$
$$n_e(p) = 0 \quad \text{for } p > p_F. \quad (3.32)$$

The Fermi momentum is determined by the electron density through eq. (3.2), i.e. $\int_0^{p_F} n_e(p) \, dp = n_e$, which yields

$$p_F = h \left( \frac{3}{8\pi n_e} \right)^{1/3}. \quad (3.33)$$

The pressure of a completely degenerate electron gas is now easy to compute using the pressure integral eq. (3.4). It depends on whether the electrons are relativistic or not. In the non-relativistic limit we have $v = p/m$ and hence

$$P_e = \frac{1}{3} \int_0^{p_F} \frac{8\pi p^4}{m_e h^3} \, dp = \frac{8\pi}{15h^3 m_e} p_F^5 = \frac{\hbar^2}{20m_e} \left( \frac{3}{\pi} \right)^{2/3} n_e^{5/3}. \quad (3.34)$$

Using eq. (3.18) for $n_e$ this can be written as

$$P_e = K_{\text{NR}} \left( \frac{\rho}{\mu_e} \right)^{5/3} \quad \text{with} \quad K_{\text{NR}} = \frac{\hbar^2}{20m_e m_u^{5/3}} \left( \frac{3}{\pi} \right)^{2/3} = 1.0036 \times 10^{13} \text{ [cgs]}. \quad (3.35)$$

As more electrons are squeezed into the same volume, they have to occupy states with larger momenta, as illustrated in Fig. 3.2. Therefore the electron pressure increases with density, as expressed by eq. (3.35).

If the electron density is increased further, at some point the velocity of the most energetic electrons, $p_F/m_e$, approaches the speed of light. We then have to replace $v = p/m$ by the relativistic kinematics relation (3.10). In the extremely relativistic limit when the majority of electrons move at relativistic speeds, we can take $v = c$ and

$$P_e = \frac{1}{3} \int_0^{p_F} \frac{8\pi c p^3}{h^3} \, dp = \frac{8\pi c}{12h^3} p_F^4 = \frac{hc}{8} \left( \frac{3}{\pi} \right)^{1/3} n_e^{4/3}, \quad (3.36)$$
which gives

\[ P_e = K_{\text{ER}} \left( \frac{p}{\mu_e} \right)^{4/3} \]

with \[ K_{\text{ER}} = \frac{\hbar c}{8 m_u} \left( \frac{3}{\pi} \right)^{1/3} = 1.2435 \times 10^{15} \text{ [cgs]} \]. (3.37)

In the ER limit the pressure still increases with density, but with a smaller exponent (4/3 instead of 5/3). The transition between the NR regime, eq. (3.35), and the ER regime, eq. (3.37), is smooth and can be expressed as a function of \( x = p_F/m_e c \), see M\AE\ER\ER Sec. 7.7. Roughly, the transition occurs at a density \( \rho_t \) given by the condition \( p_F \approx m_e c \), which can be expressed as

\[ \rho_t \approx \mu_e m_u \frac{8\pi}{3} \left( \frac{m_e c}{\hbar} \right)^3. \] (3.38)

The relation between \( P_e \) and \( \rho \) for a completely degenerate electron gas is shown in Fig. 3.3.

**Partial degeneracy**

Although the situation of complete degeneracy is only achieved at \( T = 0 \), it is a very good approximation whenever the degeneracy is strong, i.e. when the temperature is sufficiently low, as illustrated by Fig. 3.2. It corresponds to the situation when the degeneracy parameter \( \psi \gg 0 \) in eq. (3.29). In that case eqs. (3.35) and (3.37) can still be used to calculate the pressure to good approximation.

The transition between the classical ideal gas situation and a state of strong degeneracy occurs smoothly, and is known as partial degeneracy. To calculate the pressure the full expression eq. (3.29) has to be used in the pressure integral, which becomes rather complicated. The integral then depends on \( \psi \), and can be expressed as one of the so-called Fermi-Dirac integrals, see M\AE\ER\ER Sec. 7.7 for details (the other Fermi-Dirac integral relates to the internal energy density \( U \)). The situation of partial degeneracy corresponds to \( \psi \sim 0 \).

When \( \psi \ll 0 \) the classical description is recovered, i.e. eq. (3.29) becomes the Maxwell-Boltzmann distribution. In that case \( 1/(e^{(p^2/2m_kT)+\psi} + 1) = e^{-(p^2/2m_kT)+\psi} \) and therefore

\[ \frac{2}{\hbar^3} e^{\psi} = \frac{n_e}{(2\pi m_e kT)^{3/2}} \]

or \( \psi = \ln \frac{\hbar^3 n_e}{2(2\pi m_e kT)^{3/2}} \).
This only holds for $\psi \ll 0$, but more generally it can be shown that $\psi = \psi(n_e/T^2/3)$. We have to consider (partial) degeneracy if $\psi \gtrsim 0$, i.e. if

$$n_e \gtrsim \frac{2(2\pi m_e kT)^{3/2}}{h^3}.$$  \hspace{1cm} (3.39)

The limit of strong (almost complete) degeneracy is reached when $n_e$ is roughly a factor 10 higher.

### Importance of electron degeneracy in stars

As a star, or its core, contracts the density may become so high that the electrons become degenerate and exert a (much) higher pressure than they would if they behaved classically. Since in the limit of strong degeneracy the pressure no longer depends on the temperature, this degeneracy pressure can hold the star up against gravity, regardless of the temperature. Therefore a degenerate star does not have to be hot to be in hydrostatic equilibrium, and it can remain in this state forever even when it cools down. This is the situation in white dwarfs.

The importance of relativity is that, when a degenerate star becomes more compact and the density increases further, the pressure increases less steeply with density. This has important consequences for massive white dwarfs, and we shall see that it implies that there is a maximum mass for which white dwarfs can exist (the Chandrasekhar mass).

We note that although electron degeneracy can be (very) important in stars, degeneracy of the ions is not. Since the ions have masses $\gtrsim 2000$ larger than electrons, their momenta ($p = \sqrt{2m\varepsilon}$) are much larger at energy equipartition, and the condition (3.39) above (with $m_e$ replaced by $m_{ion}$) implies that much higher densities are required at a particular temperature. In practice this never occurs: before such densities are reached the protons in the atomic nuclei will capture free electrons, and the composition becomes one of (mostly) neutrons. Degeneracy of neutrons does become important when we consider neutron stars.

### 3.3.6 Radiation pressure

Photons can be treated as quantum-mechanical particles that carry momentum and therefore exert pressure when they interact with matter. In particular photons are bosons with $g_s = 2$ (two polarization states), so they can be described by the Bose-Einstein statistics, eq. (3.27). The number of photons is not conserved, they can be destroyed and created until thermodynamic equilibrium is achieved. This means that $\mu = 0$ in eq. (3.27) and hence

$$n(p)\, dp = \frac{2}{h^3} \frac{1}{e^{\varepsilon_p/kT} - 1} \cdot 4\pi p^2 \, dp$$  \hspace{1cm} (3.40)

Photons are completely relativistic with $\varepsilon_p = pc = \hbar\nu$, so in terms of frequency $\nu$ their distribution in LTE becomes the Planck function for blackbody radiation:

$$n(\nu)\, d\nu = \frac{8\pi}{c^3} \frac{\nu^3 \, d\nu}{e^{\hbar \nu/kT} - 1}$$  \hspace{1cm} (3.41)

Applying eqs. (3.2) and (3.3) one can show that the photon number density and the energy density of radiation are

$$n_{ph} = \int_0^\infty n(p) \, dp = bT^3$$  \hspace{1cm} (3.42)

$$U_{rad} = \int_0^\infty pc \, n(p) \, dp = aT^4$$  \hspace{1cm} (3.43)
where \( b = 20.3 \text{ cm}^{-3} \text{ K}^{-3} \) and \( a \) is the radiation constant

\[
a = \frac{8\pi^2k^4}{15h^3c^5} = 7.56 \times 10^{-15} \text{ erg cm}^{-3} \text{ K}^{-4}.
\]

Since photons are always extremely relativistic, \( P = \frac{1}{3} U \) by eq. (3.12) and the radiation pressure is given by

\[
P_{\text{rad}} = \frac{1}{3}aT^4
\]  \hspace{1cm} (3.44)

Pressure of a mixture of gas and radiation

The pressure inside a star is the sum of the gas pressure and radiation pressure,

\[
P = P_{\text{rad}} + P_{\text{gas}} = P_{\text{rad}} + P_{\text{ion}} + P_e.
\]

where \( P_{\text{rad}} \) is given by eq. (3.44) and \( P_{\text{ion}} \) by eq. (3.17). In general \( P_e \) must be calculated as described in Sect. 3.3.5. In the classical limit it is given by eq. (3.19), and in the limits of non-relativistic and extremely relativistic degeneracy by eqs. (3.35) and (3.37), respectively. If the electrons are non-degenerate then the pressure can be written as

\[
P = \frac{1}{3}aT^4 + \frac{R}{\mu} \rho T.
\]  \hspace{1cm} (3.45)

If the electrons are strongly degenerate their pressure dominates over that of the (classical) ions, so in that case \( P_{\text{ion}} \) can be neglected in the total pressure.

The fraction of the pressure contributed by the gas is customarily expressed as \( \beta \), i.e.

\[
P_{\text{gas}} = \beta P \quad \text{and} \quad P_{\text{rad}} = (1 - \beta) P.
\]  \hspace{1cm} (3.46)

3.3.7 Equation of state regimes

The different sources of pressure we have discussed so far dominate the equation of state at different temperatures and densities. In Fig. 3.4 the boundaries between these regimes are plotted schematically in the \( \log T, \log \rho \) plane.

- The boundary between regions where radiation and ideal-gas pressure dominate is defined by \( P_{\text{rad}} = P_{\text{gas}} \), giving \( T/\rho^{1/3} = 3.2 \times 10^7 \mu^{-1/3} \) when \( T \) and \( \rho \) are expressed in cgs units. (Verify this by comparing eqs. 3.21 and 3.44.) This is a line with slope \( \frac{1}{3} \) in the \( \log T \) vs \( \log \rho \) plane.

- Similarly, the boundary between the regions dominated by ideal-gas pressure and non-relativistic degenerate electron pressure can be defined by \( P_{\text{gas,ideal}} = P_{e,\text{NR}} \) as given by eq. (3.35), giving \( T/\rho^{2/3} = 1.21 \times 10^5 \mu_e^{-5/3} \) (again with \( T \) and \( \rho \) in cgs units). This is a line with slope \( \frac{2}{3} \) in the \( \log T \)-\( \log \rho \) plane.

- The approximate boundary between non-relativistic and relativistic degeneracy is given by eq. (3.38), \( \rho = 9.7 \times 10^5 \mu_e \text{ g/cm}^3 \).

- At high densities the boundary between ideal gas pressure and extremely relativistic degeneracy is found by equating eqs. (3.21) and (3.37), giving \( T/\rho^{1/3} = 1.50 \times 10^7 \mu_e^{-4/3} \) (with \( T \) and \( \rho \) in cgs units), again a line with slope \( \frac{1}{3} \).

As shown in Fig. 3.4, detailed models of zero-age (that is, homogeneous) main-sequence stars with masses between 0.1 and 100 \( M_\odot \) cover the region where ideal-gas pressure dominates the equation of state. This justifies the assumptions made in Ch. 2 when discussing the virial theorem and its consequences for stars, and when estimating temperatures in the stellar interior.

31
Figure 3.4. Left: The equation of state for a gas of free particles in the log $T$, log $\rho$ plane. The dashed lines are approximate boundaries between regions where radiation pressure, ideal gas pressure, non-relativistic electron degeneracy and extremely relativistic electron degeneracy dominate, for a composition $X = 0.7$ and $Z = 0.02$. Right: Detailed structure models for homogeneous main-sequence stars of 0.1...100 $M_\odot$ have been added (solid lines). The $1 M_\odot$ model is well within the ideal-gas region of the equation of state. In the 0.1 $M_\odot$ star electron degeneracy pressure is important, except in the outer layers (at low $\rho$ and $T$). In stars more massive than 10 $M_\odot$, radiation pressure becomes important, and it dominates in the surface layers of the 100 $M_\odot$ model.

3.4 Adiabatic processes

It is often important to consider processes that occur on such a short (e.g. hydrodynamical) timescale that there is no heat exchange with the environment; such processes are adiabatic. To derive the properties of stellar interiors under adiabatic conditions we need several thermodynamic derivatives. We therefore start from the laws of thermodynamics.

The first law of thermodynamics states that the amount of heat absorbed by a system ($\delta Q$) is the sum of the change in its internal energy ($\delta U$) and the work done on the system ($\delta W = P \delta V$). The second law of thermodynamics states that, for a reversible process, the change in entropy equals the change in the heat content divided by the temperature. Entropy is a state variable, unlike the heat content. For a unit mass (1 gram) of matter the combination of these laws can be expressed as

$$dq = T \, ds = du + P \, dv = du - \frac{P}{\rho^2} \, d\rho.$$  \hspace{1cm} (3.47)

Here $dq$ is the change in heat content, $du$ is the change in internal energy ($u = U/\rho$ is the specific internal energy, i.e. per gram), $s$ is the specific entropy (i.e. the entropy per unit mass) and $v = 1/\rho$ is the volume of a unit mass. Note that $du$ and $ds$ are exact differentials, whereas $dq$ is not.

**Differential form of the equation of state** To compute general expressions for thermodynamic derivatives such as the specific heats and the adiabatic derivatives it is useful to write the equation of state in differential form, i.e.

$$\frac{dP}{P} = \chi_T \frac{dT}{T} + \chi_\rho \frac{d\rho}{\rho},$$  \hspace{1cm} (3.48)
where $\chi_T$ and $\chi_\rho$ are defined as

$$
\chi_T = \left( \frac{\partial \log P}{\partial \log T} \right)_{\rho,X_i},
$$

$$
\chi_\rho = \left( \frac{\partial \log P}{\partial \log \rho} \right)_{T,X_i}.
$$

The subscript $X_i$ means that the composition is held constant as well. In a general equation of state $\chi_T$ and $\chi_\rho$ can depend on $T$ and $\rho$ themselves, but if they are (approximately) constant then we can write the equation of state in power-law form:

$$
P = P_0 \rho^{\chi_\rho} T^{\chi_T}.
$$

For example, for an ideal gas without radiation we have $\chi_T = \chi_\rho = 1$, while for a radiation-dominated gas $\chi_T = 4$ and $\chi_\rho = 0$.

### 3.4.1 Specific heats

The specific heats at constant volume $c_V$ and at constant pressure $c_P$ for a unit mass of gas follow from eq. (3.47):

$$
c_V = \left( \frac{dq}{dT} \right)_v = \left( \frac{\partial u}{\partial T} \right)_v,
$$

$$
c_P = \left( \frac{dq}{dT} \right)_p = \left( \frac{\partial u}{\partial T} \right)_p - \frac{P}{\rho^2} \left( \frac{\partial \rho}{\partial T} \right)_p.
$$

where a partial derivative taken at constant $v$ is the same as one taken at constant $\rho$. For an ideal gas, with $u = U/\rho = \frac{3}{2}P/\rho$, we obtain from eq. (3.21) the familiar result $c_V = \frac{3}{2}R/\mu$. For a radiation-dominated gas, eq. (3.43) yields $c_V = 4\alpha T^3/\rho$. Using thermodynamic transformations and some algebraic manipulation (see Appendix 3.A), it follows quite generally that the specific heats are related by

$$
c_P - c_V = \frac{P}{\rho T} \frac{\chi_T^2}{\chi_\rho}.
$$

For an ideal gas this amounts to $c_P - c_V = R/\mu$, and therefore $c_P = \frac{5}{3}R/\mu$. For a radiation-dominated gas $\chi_\rho = 0$ and hence $c_P \to \infty$: indeed, since $P_{\text{rad}}$ only depends on $T$, a change in temperature cannot be performed at constant pressure.

The ratio of specific heats is denoted as $\gamma$:

$$
\gamma = \frac{c_P}{c_V} = 1 + \frac{P}{\rho T c_V} \frac{\chi_T^2}{\chi_\rho},
$$

so that $\gamma = \frac{5}{3}$ for an ideal gas.

#### Expressions for $dq$

It is often useful to have expressions for the change in heat content $dq$ (eq. 3.47) in terms of variations of $T$ and $\rho$ or $T$ and $P$. Making use of the specific heats one can derive (see Appendix 3.A)

$$
dq = T \, ds = c_V \,dT - \chi_T \frac{P}{\rho^2} \, d\rho = c_P \,dT - \frac{\chi_T}{\chi_\rho} \frac{dP}{\rho}.
$$
### 3.4.2 Adiabatic derivatives

The thermodynamic response of a system to adiabatic changes is measured by the so-called *adiabatic derivatives*. Two of these have special importance for stellar structure:

- **The adiabatic exponent** $\gamma_{\text{ad}}$ measures the response of the pressure to adiabatic compression or expansion, i.e. to a change in the density. It is defined as
  \[
  \gamma_{\text{ad}} = \left( \frac{\partial \log P}{\partial \log \rho} \right)_{\text{ad}}
  \]  
  (3.56)
  where the subscript ’ad’ means that the change is performed adiabatically, that is, at constant entropy. If $\gamma_{\text{ad}}$ is constant then $P \propto \rho^{\gamma_{\text{ad}}}$ for adiabatic changes. As we shall see later, $\gamma_{\text{ad}}$ is related to the *dynamical stability* of stars.

- **The adiabatic temperature gradient** is defined as
  \[
  \nabla_{\text{ad}} = \left( \frac{\partial \log T}{\partial \log P} \right)_{\text{ad}}
  \]  
  (3.57)
  It is in fact another exponent that describes the behaviour of the temperature under adiabatic compression or expansion ($T \propto P^{\nabla_{\text{ad}}}$ if $\nabla_{\text{ad}}$ is constant), which turns out to be important for stability against convection.

#### The adiabatic exponent

For an adiabatic process $dq = 0$ in eq. (3.47) and therefore

\[
\frac{du}{d\rho} = \frac{P}{\rho^2} \frac{d\rho}{d\rho}.
\]  
(3.58)

We have seen in Sect. 3.3.1 that for a perfect gas of free particles the internal energy density $U$ is proportional to $P$, in both the NR and ER limits. For such a simple system we can therefore write, as we did in Sect. 2.3,

\[
u = \frac{P}{\rho} \tag{3.59}
\]

with $\phi$ a constant (between $\frac{3}{2}$ and 3). If we differentiate this and substitute into eq. (3.58) we obtain for an adiabatic change

\[
\frac{dP}{P} = \phi \frac{1}{\phi} \frac{d\rho}{\rho}.
\]  
(3.60)

Therefore, according to the definition of $\gamma_{\text{ad}}$ (eq. 3.56),

\[
\gamma_{\text{ad}} = \phi + \frac{1}{\phi} \quad \text{(for a simple, perfect gas)}.
\]  
(3.61)

---

2In many textbooks one finds instead the adiabatic exponents $\Gamma_1$, $\Gamma_2$, and $\Gamma_3$ introduced by Chandrasekhar. They are defined, and related to $\gamma_{\text{ad}}$ and $\nabla_{\text{ad}}$, as follows:

\[
\Gamma_1 = \left( \frac{\partial \log P}{\partial \log \rho} \right)_{\text{ad}} = \gamma_{\text{ad}}, \quad \quad \Gamma_2 = \left( \frac{\partial \log P}{\partial \log T} \right)_{\text{ad}} = \frac{1}{\nabla_{\text{ad}}}, \quad \quad \Gamma_3 = \left( \frac{\partial \log T}{\partial \log \rho} \right)_{\text{ad}} + 1.
\]

They obey the relation

\[
\frac{\Gamma_1}{\Gamma_3 - 1} = \frac{\Gamma_2}{\Gamma_2 - 1}.
\]
• for non-relativistic particles (e.g. a classical ideal gas, NR degenerate electrons) \( \phi = \frac{3}{2} \) and therefore \( \gamma_{ad} = \frac{5}{3} \)
• for extremely relativistic particles (e.g. photons, ER degenerate electrons) \( \phi = 3 \) and therefore \( \gamma_{ad} = \frac{4}{3} \)
• for a mixture of gas and radiation \( (0 \leq \beta \leq 1) \) and/or moderately relativistic degenerate electrons, \( \frac{4}{3} \leq \gamma_{ad} \leq \frac{5}{3} \)

For a general equation of state, described by eq. (3.48), one can derive (see Appendix 3.A)

\[
\gamma_{ad} = \chi_{\rho} + \frac{P}{\rho T c_v} \chi_T^2.
\] (3.62)

Therefore \( \gamma_{ad} \) is related to the ratio of specific heats (eq. 3.54), \( \gamma_{ad} = \gamma \chi_{\rho} \). The \( \gamma \)'s are equal if \( \chi_{\rho} = 1 \) (as in the case of an ideal gas).

The adiabatic temperature gradient By writing eq. (3.56) as \( \frac{dP}{P} = \gamma_{ad} \frac{dp}{\rho} \) for an adiabatic change, and eliminating \( dp \) with the help of eq. (3.48), we obtain a general relation between the adiabatic temperature gradient \( \nabla_{ad} \) and the adiabatic exponent \( \gamma_{ad} \):

\[
\nabla_{ad} = \frac{\gamma_{ad} - \chi_{\rho}}{\gamma_{ad} \chi_T}.
\] (3.63)

This gives the following limiting cases:

• for an ideal gas without radiation \( (\beta = 1) \) we have \( \chi_T = \chi_{\rho} = 1 \), which together with \( \gamma_{ad} = \frac{5}{3} \) gives \( \nabla_{ad} = \frac{2}{3} = 0.4 \).
• for a radiation-dominated gas \( (\beta = 0) \) \( \chi_T = 4 \) and \( \chi_{\rho} = 0 \) so that \( \nabla_{ad} = \frac{1}{4} = 0.25 \).

For a general equation of state one has to consider the general expression for \( \gamma_{ad} \) (eq. 3.62) in eq. (3.63). From the expression of \( dq \) in terms of \( dT \) and \( dP \) (3.55) it follows that

\[
\nabla_{ad} = \frac{P}{\rho T c_p} \chi_T.
\] (3.64)

This means that for a general non-adiabatic process we can write eq. (3.55) as

\[
dq = c_p \left( dT - \nabla_{ad} \frac{T}{P} dP \right).
\] (3.65)

which will prove to be a useful relation later on.

We give some important results without derivations, which can be found in K&W Chapters 13.2 and 16.3 or in Hansen Chapter 3.7:

• for a mixture of gas and radiation with \( 0 < \beta < 1 \), \( \nabla_{ad} \) and \( \gamma_{ad} \) both depend on \( \beta \) and take on intermediate values, i.e. \( 0.25 < \nabla_{ad} < 0.4 \).
• for a non-relativistic degenerate gas, we have to consider that although electrons dominate the pressure, there is a (tiny) temperature dependence due to the ion gas which must be taken into account in calculating \( \chi_T \) and therefore \( \nabla_{ad} \). After some manipulation it can be shown that in this case \( \nabla_{ad} = 0.4 \), as for the ideal classical gas.
• for an extremely relativistic degenerate gas one also has to consider that while the electrons are relativistic, the ions are still non-relativistic. It turns out that in this limit \( \nabla_{ad} = 0.5 \).
3.5 Ionization

We have so far implicitly assumed complete ionization of the gas, i.e. that it consists of bare atomic nuclei and free electrons. This is a good approximation in hot stellar interiors, where \( T > 10^6 \) K so that typical energies \( kT \) are much larger than the energy needed to ionize an atom, i.e. to knock off a bound electron. In the cooler outer layers of a star, however, we need to consider the partial ionization of the elements. In this case quasi-static changes of the state variables (\( \rho \) and \( T \)) will lead to changes in the degree of ionization. This can have a large effect on the thermodynamic properties of the gas, e.g. on \( \gamma_{ad} \) and \( \nabla_{ad} \).

In LTE the number densities of ionized and neutral species are determined by the Saha equation

\[
\frac{n_{r+1}}{n_r} \frac{n_e}{n_e} = \frac{u_{r+1}}{u_r} \frac{(2\pi m_e kT)^{3/2}}{h^3} e^{-\chi_r/kT} \tag{3.66}
\]

where \( n_r \) and \( n_{r+1} \) indicate the number densities of the \( r \)-th and \( r+1 \) times ionized nuclei, \( \chi_r \) is the ionization potential, i.e. the energy required to remove the \( r \)-th bound electron, and \( u_r \) and \( u_{r+1} \) are the partition functions. The partition functions depend on \( T \) but can in most cases be approximated by the statistical weights of the ground states of the bound species. (This equation can be derived from statistical mechanics, e.g. see K&W Chapter 14.1.)

3.5.1 Ionization of hydrogen

As an example, we consider the simple case where the gas consists only of hydrogen. Then there are just three types of particle, electrons and neutral and ionized hydrogen, with \( u_H = u_0 = 2 \) and \( u_{H^+} = u_1 = 1 \). We write their number densities as \( n_+ \) and \( n_0 \) so that

\[
\frac{n_+}{n_0} \frac{n_e}{n_e} = \frac{(2\pi m_e kT)^{3/2}}{h^3} e^{-\chi_H/kT} \tag{3.67}
\]

where \( \chi_H = 13.6 \) eV. The gas pressure is given by \( P_{gas} = (n_0 + n_+ + n_e)kT \) and the density is \( \rho = (n_0 + n_+) m_u \). The degree of ionization is defined as

\[
x = \frac{n_+}{n_0 + n_+} \tag{3.68}
\]

so that \( P_{gas} \) can be written in terms of the degree of ionization

\[
P_{gas} = (1 + x) R \rho T \tag{3.69}
\]

We can then rewrite Saha’s equation as

\[
\frac{x^2}{1 - x^2} = \frac{(2\pi m_e)^{3/2} (kT)^{5/2}}{h^3} \frac{P_{gas}}{e^{-\chi_H/kT}} \tag{3.70}
\]

We see that the degree of ionization increases with \( T \), as expected since more atoms are broken up by the energetic photons. However, \( x \) decreases with gas pressure (or density) when \( T \) is kept constant, because this increases the probability of recombination which is proportional to \( n_e \). From eq. (3.69) we see that the mean molecular weight \( \mu = 1/(1 + x) \) decreases as hydrogen becomes ionized (one atomic mass is divided over two particles).

To estimate the effect on the thermodynamic properties of the gas, we note that in the case of partial ionization the internal energy has a contribution from the available potential energy of recombination. Per unit volume this contribution is equal to \( n_+ \chi_H \), so per unit mass it equals \( n_+ \chi_H / \mu = x \chi_H / m_u \). Thus

\[
u = \frac{3}{2} \frac{P_{gas}}{\rho} + x \frac{\chi_H}{m_u} = \frac{3}{2} (1 + x) \gamma RT + x \frac{\chi_H}{m_u}. \tag{3.71}
\]
A small increase in temperature increases the degree of ionization, which results in a large amount of energy being absorbed by the gas. In other words, the specific heat of a partially ionized gas will be much larger than for an un-ionized gas, or for a completely ionized gas (in the latter case \( x = 1 \) so that the second term in eq. (3.71) becomes a constant and therefore irrelevant).

Now consider what happens if the gas is adiabatically compressed. Starting from neutral hydrogen, for which \( \nabla_{ad} = 0.4 \), the temperature initially increases as \( T \propto P^{0.4} \). Further compression (work done on the gas) increases \( u \), but when partial ionization sets in most of this energy goes into raising the degree of ionization (second term of eq. 3.71) and only little into raising the temperature (first term). In other words, \( T \) increases less strongly with with \( P \), and therefore \( \nabla_{ad} < 0.4 \). A detailed calculation (e.g. see K&W Chapter 14.3) shows that under typical conditions \( \nabla_{ad} \) reaches a minimum value of \( \approx 0.1 \) when \( x \approx 0.5 \). As the gas becomes almost fully ionized, \( \nabla_{ad} \) rises back to 0.4. The variation of \( \nabla_{ad} \) with temperature for a pure hydrogen gas is shown in the left panel of Fig. 3.5 for different values of the density.

The decrease of \( \nabla_{ad} \) in partial ionization zones can induce convection in the outer layers of stars, as we shall see in Ch. 5. Similarly it can be shown that \( \gamma_{ad} \) decreases in partial ionization zones, from \( \frac{5}{3} \) to \( \gamma_{ad} \approx 1.2 \) when \( x \approx 0.5 \). This has consequences for the stability of stars, as we shall also see.
3.5.2 Ionization of a mixture of gases

In a mixture of gases the situation becomes more complicated because many, partly ionized species have to be considered, the densities of which all depend on each other (see e.g. K&W Chapter 14.4-14.5). However the basic physics remains the same as considered above for the simple case of pure hydrogen. The effect on the thermodynamic properties is that e.g. \( \nabla_{ad} \) can show additional deviations below 0.4 at different temperatures, especially where helium (the second-most abundant element in stars) is partially ionized. This is illustrated in Fig. 3.5b which shows the variation of \( \nabla_{ad} \) with temperature in a homogeneous model for the initial Sun.

3.5.3 Pressure ionization

As \( \rho \) increases indefinitely, the Saha equation gives \( x \to 0 \), i.e. ionized gas recombines to form atoms. This is obviously nonsense at very high density, and becomes incorrect when the average distance \( d \) between ions becomes less than an atomic radius. In this situation the ionization energy is suppressed (there are fewer bound excited states; see Fig. 3.6), a situation known as pressure ionization.

Consider the case of hydrogen: the volume per H atom is \( \frac{1}{n_H} \) so that \( d = \left( \frac{4\pi}{3} n_H \right)^{-1/3} \). Pressure ionization sets in when \( d \approx a_0 = 5 \times 10^{-9} \text{ cm} \) (the Bohr radius). This implies

\[
\frac{1}{\frac{4\pi}{3} a_0^3} \quad \text{or} \quad \rho = n_H m_H \geq 3 \text{ g cm}^{-3}.
\]

Other elements are pressure-ionized at similar values of the density, within an order of magnitude. At densities \( \geq 10 \text{ g cm}^{-3} \), therefore, we can again assume complete ionization.

Fig. 3.7 shows the approximate boundary in the density-temperature diagram between neutral and ionized hydrogen according the Saha equation for \( \rho < 1 \text{ g cm}^{-3} \), and as a result of pressure ionization at higher densities.

3.6 Other effects on the equation of state

3.6.1 Coulomb interactions and crystallization

We have so far ignored the effect of electrostatic or Coulomb interactions between the ions and electrons in the gas. Is this a reasonable approximation, i.e. are the interaction energies indeed small compared to the kinetic energies, as we have assumed in Sect. 3.3?

The average distance between gas particles (with mass \( A m_a \)) is \( d \approx \left( \frac{4\pi}{3} n \right)^{-1/3} \) where \( n \) is the number density, \( n = \rho / (A m_a) \). The typical Coulomb energy per particle (with charge \( Z e \)) is \( e_C \approx Z^2 e^2 / d \), while the average kinetic energy is \( e_{\text{kin}} = \frac{3}{2} kT \). The ratio of Coulomb energy to kinetic energy is usually called the Coulomb parameter \( \Gamma_C \), defined as

\[
\Gamma_C = \frac{Z^2 e^2}{d kT} = \frac{Z^2 e^2}{kT} \left( \frac{4\pi \rho}{3A m_a} \right)^{1/3} = 2.275 \times 10^5 \frac{Z^2}{A^{1/3}} \frac{\rho^{1/3}}{T},
\]  

(3.72)
where in the last equality the numerical factor is in cgs units. We see that Coulomb interactions increase in importance at high densities or low temperatures. Roughly, Coulomb interactions start to become important in stellar interiors when $\Gamma_C \gtrsim 1$.

To estimate the typical value of $\Gamma_C$ in stellar interiors we approximate $\rho \approx \bar{\rho} = M/(4\pi R^3)$, and we approximate $T$ by the average temperature estimated from the virial theorem, $T \approx \bar{T} \approx \frac{1}{3} \frac{A m_u GM}{k R}$ (eq. 2.29). Ignoring factors of order unity, we get

$$\Gamma_C \approx 0.01 \frac{Z^2}{A^{4/3}} \left( \frac{M}{M_{\odot}} \right)^{-2/3}. \quad (3.73)$$

The ratio $Z^2/A^{4/3}$ depends on the composition, and represents an average over the constituents of the gas. In stars mostly composed of hydrogen, $A \approx 1$ and $Z \approx 1$, and we find that in the Sun the Coulomb energy contributes of the order of 1% to the particle energies (and hence has a similar effect on the pressure). We are therefore justified in ignoring Coulomb interactions in stars similar to or more massive than the Sun. However, eq. (3.73) shows that in low-mass stars Coulomb interactions can start to contribute significantly. This can also be seen by comparing Fig. 3.4 and Fig. 3.7, where the location of the condition $\Gamma_C = 1$ is indicated in the $\rho$-$T$ diagram. Detailed models of low-mass stars need to take this effect into account. For $M \lesssim 10^{-3} M_{\odot}$ the Coulomb energies dominate. Such objects are not stars but planets (Jupiter’s mass is about $10^{-3} M_{\odot}$). Calculations of the structure of planets requires a much more complicated equation of state than for stars.

**Crystallization**

If $\Gamma_C \gg 1$ the thermal motions of the ions are overwhelmed by the Coulomb interactions. In this situation the ions will tend to settle down into a conglomerate with a lower energy, in other words they will form a crystalline lattice. Detailed estimates indicate that this transition takes place at a critical value of $\Gamma_C \approx 170$. This condition is also indicated in Fig. 3.4 for a pure hydrogen gas. In reality, this situation will never occur in hydrogen-rich stellar interiors, but it can take place in cooling...
white dwarfs (in which the temperature gradually decreases with time while the density remains constant). White dwarfs are usually composed of carbon and oxygen, so in this case we have to take into account the composition which raises the temperature at which the transition occurs (the ‘melting’ temperature) by a factor $Z^2/A^{1/3}$ according to eq. (3.72).

Finally we note that crystallization only occurs in the region where the electrons are strongly degenerate. You may verify that the Coulomb interaction energy between electrons and ions $(Ze^2/d)$ is always smaller than the typical electron energy $(p_F^2/2m_e)$. The electrons therefore behave as a free degenerate gas, even if the ions form a crystalline structure.

### 3.6.2 Pair production

A very different process can take place at very high temperatures and relatively low densities. A photon may turn into an electron-positron pair if its energy $h\nu$ exceeds the rest-mass energy of the pair, $h\nu > 2m_ec^2$. This must take place during the interaction with a nucleus, since otherwise momentum and energy cannot both be conserved. Pair production takes place at a typical temperature $kT \approx h\nu \approx 2m_ec^2$, or $T \approx 1.2 \times 10^{10}$ K. However, even at $T \sim 10^9$ K the number of energetic photons in the tail of the Planck distribution (eq. 3.41) is large enough to produce a large number of $e^+e^-$ pairs. The newly created positrons tend to be annihilated quickly by the inverse reaction $(e^+ + e^- \rightarrow 2\gamma)$, as a result of which the number of positrons reaches equilibrium. At a few times $10^9$ K, depending on the electron density, the number of positrons is a significant fraction of the number of electrons.

Pair production is similar to an ionization process: an increase in temperature leads to an increase in the number of particles at the expense of the photon energy (and pressure). Therefore pair production gives rise to a decrease of the adiabatic gradient $\gamma_{ad}$ and of $\nabla_{ad}$, similar to partial ionization. This is the main importance of pair production for stellar evolution: it affects the stability of very massive stars in advanced stages of evolution (when their temperature may reach values in excess of $10^9$ K) and can trigger their collapse.

---

### Suggestions for further reading

The contents of this chapter are also covered by Chapter 7 of Maeder and by Chapters 13 to 16 of Kippenhahn & Weigert. However, a more elegant derivation of the equation of state, which is also more consistent with the way it is derived in these lecture notes, is given in Chapter 3 of Hansen, Kawaler & Trimble. Explicit expressions for many of the results that are only mentioned here can be found in this book.

---

### Exercises

#### 3.1 Conceptual questions

These questions are intended to test your understanding of the lectures. Try to answer them without referring to the lecture notes.

(a) What do we mean by local thermodynamic equilibrium (LTE)? Why is this a good assumption for stellar interiors? What is the difference between LTE and thermal equilibrium (as treated in Ch. 2)?

(b) In what type of stars does degeneracy become important? Is it important in main-sequence stars? Is it more important in high mass or low mass MS stars?
(c) Explain qualitatively why for degenerate matter, the pressure increases with the density.

(d) Why do electrons become relativistic when they are compressed into a smaller volume? Why does the pressure increase less steeply with the density in this case?

(e) In the central region of a star we find free electrons and ions. Why do the electrons become degenerate first? Why do the ions never become degenerate in practice?

3.2 Mean molecular weight

Derive a general expression for the mean molecular weight of an ionized gas, as a function of composition $X, Y, Z$. Assume that, for elements heavier than H, nuclei are composed of equal number of protons and neutrons, so that the nuclear charge $Z_i$ is half of the mass number $A_i$.

3.3 The $\rho − T$ plane

Consider a gas of ionized hydrogen. In the $\rho − T$ plane compute the approximate boundary lines between the regions where:

(a) radiation pressure dominates,

(b) the electrons behave like a classical ideal gas,

(c) the electrons behave like a degenerate gas,

(d) the electrons are relativistically degenerate.

3.4 The pressure of a gas of free particles

In this exercise you will derive some important relations from this chapter for yourself.

(a) Suppose that the particles in a gas have momenta distributed as $n(p)\, dp$. Show that the pressure can be expressed by eq. (3.4).

(b) For classical particles in LTE, the momentum distribution is given by the Maxwell-Boltzmann distribution, eq. (3.13). Calculate the pressure using eq. (3.4). Does the result look familiar?

(c) Show that for a gas of free, non-relativistic particles $P = \frac{1}{3} U$ (eq. 3.11), where $U$ is the internal energy density. Show that in the extremely relativistic limit $P = \frac{1}{3} U$ (eq. 3.12).

(d) Electrons are fermions with 2 spin states. Explain why the maximum number of electrons per volume with momentum $p$ can be written as eq. (3.28).

(e) In the extreme case of complete degeneracy, $T \to 0$, the electrons fill up all available quantum states up to a maximum $p_F$, the Fermi momentum. Show that

$$p_F = \hbar \left(\frac{3n_e}{8\pi} \right)^{\frac{1}{3}}$$

(f) Show that the pressure as function of the density for a non-relativistic degenerate electron gas can be written as

$$P = K_{NR} \left(\frac{\rho}{\mu_e}\right)^x$$

and derive an expression for $K_{NR}$ and $x$.

(g) Show that the pressure as function of the density for an extremely relativistic degenerate electron gas can be written as

$$P = K_{ER} \left(\frac{\rho}{\mu_e}\right)^y$$

and derive an expression for $K_{ER}$ and $y$. 

41
Photons are bosons, and the distribution of their momenta is given by the Planck function (eq. 3.27).

Show that in this case
\[ U \propto T^4 \]
(Hint: to derive an expression for the proportionality constant \( a \), you might want to use Mathematica or a list of standard integrals.)

(i) Now use (c) to show that the radiation pressure is given by \( P_{\text{rad}} = \frac{1}{3} a T^4 \).

### 3.5 Adiabatic derivatives

(a) Use the first law of thermodynamics to show that, for an ideal gas in an adiabatic process,
\[ P \propto \rho^{\gamma_{ad}} \]
and give a value for the adiabatic exponent \( \gamma_{ad} \).

(b) Use the ideal gas law in combination with eq. (3.74) to show that
\[ \nabla_{ad} = \left( \frac{d \ln T}{d \ln P} \right)_{ad, id} = 0.4. \]

(c) The quantity \( \nabla_{ad} \) is referred to as the *adiabatic temperature gradient*. Normally you would use the term ‘gradient of a quantity \( A \)’ for \( dA/dr \), or if you use mass coordinates instead of radius coordinates, \( dX/dm \). Do you understand why \( \nabla_{ad} \) can be referred to as a temperature ‘gradient’?

(d) (*) Show that for a mixture of an ideal gas plus radiation, the adiabatic exponent is given by
\[ \gamma_{ad} = \frac{32 - 24\beta - 2\beta^2}{24 - 21\beta}, \]
where \( \beta = P_{\text{gas}}/P \).
(Hints: write down the equation of state for the mixture in differential form as in eq. (3.48), and express \( \chi_T \) and \( \chi_{\rho} \) in terms of \( \beta \). Then apply the first law of thermodynamics for an adiabatic process.)

(e) (*) What is the value of \( \gamma_{ad} \) in the limit where radiation dominates and where pressure dominates? Does this look familiar?

### 3.6 Ionization effects

(a) The particles in an ionized gas are charged and therefore undergo electrostatic (Coulomb) interactions. Why can we nevertheless make the ideal-gas assumption in most stars (i.e. that the internal energy of the gas is just the sum of the kinetic energies of the particles)? For which stars do Coulomb interactions have a significant effect?

(b) Why does the gas in the interior of a star become pressure-ionized at high densities?

(c) Explain qualitatively why partial ionization leads to \( \nabla_{ad} < \nabla_{ad, \text{ideal}} = 0.4 \), in other words: why does adiabatic compression lead to a smaller temperature increase when the gas is partly ionized, compared to a completely ionized (or unionized) gas?
3.A Appendix: Thermodynamic relations

In this Appendix we derive some of the thermodynamic relations that were given without proof in Chapter 3. The first law of thermodynamics states that the heat added to a mass element of gas is the sum of the change in its internal energy and the work done by the mass element. Taking the element to be of unit mass, we can write this as

\[ dq = du + P \, dv = du - \frac{P}{\rho^2} \, d\rho. \]  

(3.75)

because the volume of a unit mass is \( v = 1/\rho \). We can write the change in the internal energy of a unit mass in terms of the changes in the state variables \((T, \rho)\) as

\[ du = \frac{\partial u}{\partial T} \, dT + \frac{\partial u}{\partial \rho} \, d\rho. \]  

(3.76)

The change in the entropy per unit mass, \( ds = dq/T \), is therefore

\[ ds = \frac{dq}{T} = \frac{1}{T} \left( \frac{\partial u}{\partial T} \right)_\rho \, dT + \frac{1}{T} \left( \frac{\partial u}{\partial \rho} \right)_T \, d\rho - \frac{P}{\rho^2} \, d\rho. \]  

(3.77)

Because \( s \) is a function of state, \( \partial^2 s/\partial \rho \partial T = \partial^2 s/\partial T \partial \rho \), which means that

\[ \frac{1}{T} \frac{\partial^2 u}{\partial T \partial \rho} = \frac{\partial}{\partial T} \left[ \frac{1}{T} \left( \frac{\partial u}{\partial \rho} \right)_T - \frac{P}{\rho^2 T} \right]. \]  

(3.78)

where the \( \partial/\partial T \) on the right-hand side should be taken at constant \( \rho \). Working out the right-hand side allows us to eliminate the second derivative of \( u \), giving

\[ \frac{1}{T^2} \left( \frac{\partial u}{\partial \rho} \right)_T = \frac{P}{\rho^2 T} - \frac{1}{\rho^2 T} \left( \frac{\partial P}{\partial T} \right)_\rho. \]

With the definition of \( \chi_T \) (eq. 3.49) we can write \( \left( \partial P/\partial T \right)_\rho = \chi_T P/T \), and thus

\[ \left( \frac{\partial u}{\partial \rho} \right)_T = (1 - \chi_T) \frac{P}{\rho^2}. \]  

(3.79)

Specific heats

The definitions of the specific heats at constant volume and at constant pressure are

\[ c_v \equiv \frac{dq}{dT}_v = \left( \frac{\partial u}{\partial T} \right)_v, \]  

(3.80)

\[ c_p \equiv \frac{dq}{dT}_p = \left( \frac{\partial u}{\partial T} \right)_p - \frac{P}{\rho^2} \left( \frac{\partial P}{\partial T} \right)_p. \]  

(3.81)

To work out an expression for \( c_p \), we need \( \left( \partial u/\partial T \right)_p \) and \( \left( \partial P/\partial T \right)_p \). To start with the latter, we use the differential form of the equation of state (3.48). At constant pressure \( dP = 0 \) this gives

\[ \chi_p \frac{d\rho}{\rho} = -\chi_T \frac{dT}{T} \quad \Rightarrow \quad \left( \frac{d\rho}{\partial T} \right)_p = -\frac{\rho}{T} \frac{\chi_T}{\chi_p}. \]  

(3.82)

To obtain an expression for \( \left( \partial u/\partial T \right)_p \) we use eq. (3.76), which we can write as

\[ \frac{du}{dT} = \left( \frac{\partial u}{\partial T} \right)_\rho + \left( \frac{\partial u}{\partial \rho} \right)_T \frac{d\rho}{dT}. \]  

43
and therefore
\[
\frac{\partial u}{\partial T} = \frac{\partial u}{\partial T} + \left( \frac{\partial u}{\partial \rho} \right)_T \frac{\partial \rho}{\partial T} = \frac{\partial u}{\partial T} + (\chi_T - 1) \frac{\chi_T P}{\rho T}. \tag{3.83}
\]
To obtain the last equality we used eqs. (3.79) and (3.82). From the definitions (3.80) and (3.81) we thus arrive at the following relation between \(c_p\) and \(c_V\):
\[
c_p - c_V = \frac{\chi_T^2}{\chi^0} \frac{\rho}{\rho T} \tag{3.84}
\]
which is eq. (3.53).

**Expressions for \(dq\)**

It is useful to be able to write the change in heat content of a unit mass in terms of the changes in the state variables. Eq. (3.77) already shows how \(dq\) is written in terms of \(T\) and \(\rho\), i.e.
\[
dq = T \, ds = c_V \, dT - \frac{\chi_T}{\chi^0} \frac{\rho}{\rho T} \, d\rho, \tag{3.85}
\]
making use of (3.79) and (3.80). It is often useful to express \(dq\) is terms of \(T\) and \(P\), rather than \(\rho\). To do this we write \(d\rho\) with the help of eq. (3.48),
\[
d\rho = \frac{\rho}{\chi^0} \left( \frac{dP}{P} - \chi_T \frac{dT}{T} \right), \tag{3.86}
\]
so that
\[
dq = c_V \, dT - \frac{\chi_T}{\chi^0} \frac{P}{\rho T} \left( \frac{dP}{P} - \chi_T \frac{dT}{T} \right) = \left( c_V + \frac{\chi_T^2}{\chi^0} \frac{P}{\rho T} \right) \frac{dT}{T} - \frac{\chi_T}{\chi^0} \frac{1}{\rho} \frac{dP}{P}. \tag{3.87}
\]
The terms with parentheses in the last equality are simple \(c_p\), according to (3.84), and therefore
\[
dq = T \, ds = c_p \, dT - \frac{\chi_T}{\chi^0} \frac{dP}{P}. \tag{3.88}
\]

**Adiabatic derivatives**

Eq. (3.88) makes it easy to derive an expression for the adiabatic temperature gradient (3.57),
\[
\nabla_{\text{ad}} \equiv \left( \frac{d \ln T}{d \ln P} \right)_{\text{ad}}. \tag{3.89}
\]
An adiabatic change in \(T\) and \(P\) means the changes take place at constant \(s\), or with \(dq = 0\). Hence (3.88) shows that
\[
\left( \frac{dT}{dP} \right)_s = \frac{1}{\rho c_P \chi^0} \chi_T \quad \Rightarrow \quad \left( \frac{d \ln T}{d \ln P} \right)_s = \frac{P}{T} \left( \frac{dT}{dP} \right)_s = \frac{P}{\rho T c_P \chi^0}. \tag{3.90}
\]
This means
\[
\nabla_{\text{ad}} = \frac{P}{\rho T c_P \chi^0}, \tag{3.91}
\]
which is eq. (3.64). With the help of this expression we can also write (3.88) as
\[
dq = c_P \left( dT - \nabla_{\text{ad}} \frac{T}{P} \frac{dP}{P} \right). \tag{3.92}
\]
To derive an expression for the adiabatic exponent (3.56),

$$\gamma_{ad} \equiv \left( \frac{d \ln P}{d \ln \rho} \right)_{ad}, \quad (3.93)$$

we use (3.85) and (3.88) and set $dq = 0$ in both expressions. This gives

$$dT = \frac{P}{\rho^2 c_V \chi T} \frac{d \rho}{\rho} \quad \text{and} \quad dT = \frac{\chi T}{\rho c_p \chi \rho} dP.$$

Eliminating $dT$ from both expressions gives

$$\frac{dP}{P} = \frac{c_p}{c_V \chi \rho} \frac{d \rho}{\rho} \quad \Rightarrow \quad \left( \frac{d \ln P}{d \ln \rho} \right)_s = \frac{c_p}{c_V \chi \rho}.$$

This means

$$\gamma_{ad} = \frac{c_p}{c_V \chi \rho} = \gamma \chi \rho, \quad (3.94)$$

where $\gamma = c_p/c_V$ is the ratio of specific heats. Using eq. (3.84) this can also be written as

$$\gamma_{ad} = \chi \rho + \frac{P}{\rho T c_V \chi T^2}, \quad (3.95)$$

which is eq. (3.62).
Chapter 4

Polytropic stellar models

As mentioned in Sec. 2.2, the equation of hydrostatic equilibrium can be solved if the pressure is a known function of the density, \( P = P(\rho) \). In this situation the mechanical structure of the star is completely determined. A special case of such a relation between \( P \) and \( \rho \) is the polytropic relation,

\[
P = K\rho^n
\]

where \( K \) and \( n \) are both constants. The resulting stellar models are known as polytropic stellar models or simply polytropes. Polytropic models have played an important role in the historical development of stellar structure theory. Although nowadays their practical use has mostly been superseded by more realistic stellar models, due to their simplicity polytropic models still give useful insight into several important properties of stars. Moreover, in some cases the polytropic relation is a good approximation to the real equation of state. We have encountered a few examples of polytropic equations of state in Chapter 3, e.g. the pressure of degenerate electrons, and the case where pressure and density are related adiabatically.

In this brief chapter – and the accompanying computer practicum – we will derive the analytic theory of polytropes and construct polytropic models, and study to which kind of stars they correspond, at least approximately.

4.1 Polytropes and the Lane-Emden equation

If the equation of state can be written in polytropic form, the equations for mass continuity (\( \frac{dm}{dr} \), eq. 2.3) and for hydrostatic equilibrium (\( \frac{dP}{dr} \), eq. 2.12) can be combined with eq. (4.1) to give a second-order differential equation for the density:

\[
\frac{1}{\rho r^2} \frac{d}{dr} \left( r^2 \rho^{n-2} \frac{d\rho}{dr} \right) = -\frac{4\pi G K}{r^n}
\]

The exponent \( \gamma \) is often replaced by the so-called polytropic index \( n \), which is defined by

\[
n = \frac{1}{\gamma - 1} \quad \text{or} \quad \gamma = \frac{1 + \frac{1}{n}}{n}
\]

In order to construct a polytropic stellar model we have to solve eq. (4.2), together with two boundary conditions which are set in the centre, \( r = 0 \):

\[
\rho(0) = \rho_c \quad \text{and} \quad \left( \frac{d\rho}{dr} \right)_{r=0} = 0,
\]

where \( \rho_c \) is a parameter to be chosen, or determined from other constraints.
In order to simplify eq. (4.2), we define two new dimensionless variables $w$ (related to the density) and $z$ (related to the radius) by writing

$$\rho = \rho_c w^n, \quad (4.5)$$

$$r = \alpha z, \quad \text{with} \quad \alpha = \left( \frac{n + 1}{4\pi G K \rho_c^{1/n-1}} \right)^{1/2}. \quad (4.6)$$

This choice of $\alpha$ ensures that the constants $K$ and $4\pi G$ are eliminated after substituting $r$ and $\rho$ into eq. (4.2). The resulting second-order differential equation is called the Lane-Emden equation:

$$\frac{1}{z^2} \frac{d}{dz} \left( z^2 \frac{dw}{dz} \right) + w^n = 0. \quad (4.7)$$

A polytropic stellar model can be constructed by integrating this equation outwards from the centre. The boundary conditions (4.4) imply that in the centre ($z = 0$) we have $w = 1$ and $dw/dz = 0$. For $n < 5$ the solution $w(z)$ is found to decrease monotonically and to reach zero at finite $z = z_n$, which corresponds to the surface of the model.

No general analytical solution of the Lane-Emden equation exists. The only exceptions are $n = 0$, 1 and 5, for which the solutions are:

$$n = 0 : \quad w(z) = 1 - \frac{z^2}{6}, \quad z_0 = \sqrt{6}, \quad (4.8)$$

$$n = 1 : \quad w(z) = \frac{\sin z}{z}, \quad z_1 = \pi, \quad (4.9)$$

$$n = 5 : \quad w(z) = \left( 1 + \frac{z^2}{3} \right)^{-1/2}, \quad z_5 = \infty. \quad (4.10)$$

The case $n = 0$ ($\gamma = \infty$) corresponds to a homogeneous gas sphere with constant density $\rho_c$, following eq. (4.5). The solution for $n = 5$ is peculiar in that it has infinite radius; this is the case for all $n \geq 5$, while for $n < 5$ $z_n$ grows monotonically with $n$. For values of $n$ other than 0, 1 or 5 the solution must be found by numerical integration (this is quite straightforward, see the accompanying computer practicum). Table 4.1 lists the value of $z_n$ for different values of $n$, as well as several other properties of the solution that will be discussed below.

4.1.1 Physical properties of the solutions

Once the solution \( w(z) \) of the Lane-Emden equation is found, eq. (4.5) fixes the relative density distribution of the model, which is thus uniquely determined by the polytropic index \( n \). Given the solution for a certain \( n \), the physical properties of a polytropic stellar model, such as its mass and radius, are then determined by the parameters \( K \) and \( \rho_c \), as follows.

The radius of a polytropic model follows from eq. (4.6):

\[
R = \alpha z_n = \left[ \frac{(n + 1)K}{4\pi G} \rho_c^{(3-n)/2n} z_n \right]^{1/2}.
\]  
(4.11)

The mass \( m(z) \) interior to \( z \) can be obtained from integrating eq. (2.3), using eqs. (4.5), (4.6) and (4.7):

\[
m(z) = \int_0^z 4\pi r^2 \rho \, dr = -4\pi \alpha^3 \rho_c \frac{z}{z_n} \frac{dw}{dz}.
\]  
(4.12)

Hence the total mass of a polytropic model is

\[
M = 4\pi \alpha^3 \rho_c \Theta_n = 4\pi \frac{(n + 1)K}{4\pi G} \rho_c^{(3-n)/2n} \Theta_n,
\]  
(4.13)

where we have defined \( \Theta_n \) as

\[
\Theta_n \equiv \left( \frac{z}{z_n} \frac{dw}{dz} \right)_{z=z_n}.
\]  
(4.14)

By eliminating \( \rho_c \) from eqs. (4.11) and (4.13) we can find a relation between \( M, R \) and \( K \),

\[
K = N_n GM^{(n-1)/n} R^{(3-n)/n} \quad \text{with} \quad N_n = \frac{(4\pi)^{1/n}}{n + 1} \frac{\Theta_n}{z_n} \left[ \frac{z_n}{z} \right]^{(n-3)/n}.
\]  
(4.15)

Numerical values of \( \Theta_n \) and \( N_n \) are given in Table 4.1. From the expressions above we see that \( n = 1 \) and \( n = 3 \) are special cases. For \( n = 1 \) the radius is independent of the mass, and is uniquely determined by the value of \( K \). Conversely, for \( n = 3 \) the mass is independent of the radius and is uniquely determined by \( K \). For a given \( K \) there is only one value of \( M \) for which hydrostatic equilibrium can be satisfied if \( n = 3 \).

The average density \( \bar{\rho} = M/(\frac{4}{3}\pi R^3) \) of a polytropic star is related to the central density by eqs. (4.11) and (4.13) as

\[
\bar{\rho} = \left( -\frac{3}{z} \frac{dw}{dz} \right)_{z=z_n} \rho_c = \frac{3\Theta_n}{z_n} \rho_c.
\]  
(4.16)

Hence the ratio \( \rho_c/\bar{\rho} \), i.e. the degree of central concentration of a polytrope, only depends on the polytropic index \( n \). This dependence is also tabulated in Table 4.1. One may invert this relation to find the central density of a polytropic star of a given mass and radius.

The central pressure of a polytropic star follows from eq. (4.1), which can be written as

\[
P_c = K \rho_c^{(n+1)/n}.
\]

In combination with (4.15) and (4.16) this gives

\[
P_c = W_n \frac{GM^2}{R^4} \quad \text{with} \quad W_n = \frac{z_n^4}{4\pi (n+1) \Theta_n^2}.
\]  
(4.17)
Note that in our simple scaling estimate, eq. (2.14), we found the same proportionality \( P_c \propto G M^2 / R^4 \), where the proportionality constant \( W_n \) is now determined by the polytropic index \( n \) (see Table 4.1). We can eliminate \( R \) in favour of \( \rho_c \) to obtain the very useful relation

\[
P_c = C_n G M^2 / \rho_c^{4/3},
\]

where you may verify that the constant \( C_n \) is only weakly dependent on \( n \), unlike \( W_n \) in (4.17).

We give without derivation an expression for the gravitational potential energy of a polytrope of index \( n \):

\[
E_{gr} = -\frac{3}{5 - n} \frac{G M^2}{R}.
\]

(The derivation can be found in K&W Sec. 19.9 and Maeder Sec. 24.5.1.)

4.2 Application to stars

Eq. (4.15) expresses a relation between the constant \( K \) in eq. (4.1) and the mass and radius of a polytropic model. This relation can be interpreted in two very different ways:

- The constant \( K \) may be given in terms of physical constants. This is the case, for example, for a star dominated by the pressure of degenerate electrons, in either the non-relativistic limit or the extremely relativistic limit. In that case eq. (4.15) defines a unique relation between the mass and radius of a star.

- In other cases the constant \( K \) merely expresses proportionality in eq. (4.1), i.e. \( K \) is a free parameter that is constant in a particular star, but may vary from star to star. In this case there are many different possible values of \( M \) and \( R \). For a star with a given mass and radius, the corresponding value of \( K \) for this star can be determined from eq. (4.15).

In this section we briefly discuss examples for each of these two interpretations.

4.2.1 White dwarfs and the Chandrasekhar mass

Stars that are so compact and dense that their interior pressure is dominated by degenerate electrons are known observationally as white dwarfs. They are the remnants of stellar cores in which hydrogen has been completely converted into helium and, in most cases, also helium has been fused into carbon and oxygen. Since the pressure of a completely degenerate electron gas is a function of density only (Sec. 3.3.5), the mechanical structure if a white dwarf is fixed and is independent of temperature. We can thus understand some of the structural properties of white dwarfs by means of polytropic models.

We start by considering the equation of state for a degenerate, non-relativistic electron gas. From eq. (3.35) this can be described by a polytropic relation with \( n = 1.5 \). Since the corresponding \( K \) is determined by physical constants, eq. (4.15) shows that such a polytrope follows a mass-radius relation of the from

\[
R \propto M^{-1/3}.
\]

More massive white dwarfs are thus more compact, and therefore have a higher density. Above a certain density the electrons will become relativistic as they are pushed up to higher momenta by the Pauli exclusion principle. The degree of relativity increases with density, and therefore with the mass of the white dwarf, until at a certain mass all the electrons become extremely relativistic, i.e., their
speed \( v_e \rightarrow c \). In this limit the equation of state has changed from eq. (3.35) to eq. (3.37), which is also a polytropic relation but with \( n = 3 \). We have already seen above that an \( n = 3 \) polytrope is special in the sense that it has a unique mass, which is determined by \( K \) and is independent of the radius:

\[
M = 4\pi \Theta_3 \left( \frac{K}{\pi G} \right)^{3/2}.
\]  

(4.21)

This value corresponds to an upper limit to the mass of a gas sphere in hydrostatic equilibrium that can be supported by degenerate electrons, and thus to the maximum possible mass for a white dwarf. Its existence was first found by Chandrasekhar in 1931, after whom this limiting mass was named. Substituting the proper numerical values into eq. (4.21), with \( K \) corresponding to eq. (3.37), we obtain the Chandrasekhar mass

\[
M_{\text{Ch}} = 5.836 \mu_e^{-2} M_\odot.
\]  

(4.22)

White dwarfs are typically formed of helium, carbon or oxygen, for which \( \mu_e = 2 \) and therefore \( M_{\text{Ch}} = 1.46 M_\odot \). Indeed no white dwarf with a mass exceeding this limit is known to exist.

### 4.2.2 Eddington’s standard model

As an example of a situation where \( K \) is not fixed by physical constants but is essentially a free parameter, we consider a star in which the pressure is given by a mixture of ideal gas pressure and radiation pressure, eq. (3.45). In particular we make the assumption that the ratio \( \beta \) of gas pressure to total pressure is constant, i.e. has the same value in each layer of the star. Since \( P_{\text{gas}} = \beta P \) we can write

\[
P = \frac{1}{\beta} \frac{R}{\mu} \rho T,
\]  

(4.23)

while also

\[
1 - \beta = \frac{P_{\text{rad}}}{P} = aT^4 \frac{3}{3P}.
\]  

(4.24)

Thus the assumption of constant \( \beta \) means that \( T^4 \propto P \) throughout the star. If we substitute the complete expression for \( T^4 \) into eq. (4.24) we obtain

\[
P = \left( \frac{3R^4}{a\mu^4} \frac{1 - \beta}{\beta^4} \right)^{1/3} \rho^{4/3},
\]  

(4.25)

which is a polytropic relation with \( n = 3 \) for constant \( \beta \). Since we are free to choose \( \beta \) between 0 and 1, the constant \( K \) is indeed a free parameter dependent on \( \beta \).

The relation (4.25) was derived by Arthur Eddington in the 1920s for his famous ‘standard model’. He found that in regions with a high opacity \( \kappa \) (see Ch. 5) the ratio of local luminosity to mass coordinate \( l/m \) is usually small, and vice versa. Making the assumption that \( \kappa l/m \) is constant throughout the star is equivalent to assuming that \( \beta \) is constant (again, see Ch. 5). Indeed, for stars in which radiation is the main energy transport mechanism this turns out to be approximately true, even though it is a very rough approximation to the real situation. Nevertheless, the structure of stars on the main sequence with \( M \gtrsim M_\odot \) is reasonably well approximated by that of a \( n = 3 \) polytrope. Since the mass of a \( n = 3 \) polytrope is given by eq. (4.21), we see from eq. (4.25) that there is a unique relation between the mass \( M \) of a star and \( \beta \). The relative contribution of radiation pressure increases with the mass of a star. This was also noted by Eddington, who pointed out that the limited range of known stellar masses corresponds to values of \( \beta \) that are significantly different from 0 or 1.
Suggestions for further reading
Polytropic stellar models are briefly covered in Chapter 24.5 of Maeder and treated more extensively in Chapter 19 of Kippenhahn & Weigert and Chapter 7.2 of Hansen.

Exercises

4.1 The Lane-Emden equation
(a) Derive eq. (4.2) from the stellar structure equations for mass continuity and hydrostatic equilibrium. (Hint: multiply the hydrostatic equation by \( r^2 / \rho \) and take the derivative with respect to \( r \)).
(b) What determines the second boundary condition of eq. (4.4), i.e., why does the density gradient have to vanish at the center?
(c) By making the substitutions (4.3), (4.5) and (4.6), derive the Lane-Emden equation (4.7).
(d) Solve the Lane-Emden equation analytically for the cases \( n = 0 \) and \( n = 1 \).

4.2 Polytropic models
(a) Derive \( K \) and \( \gamma \) for the equation of state of an ideal gas at a fixed temperature \( T \), of a non-relativistic degenerate gas and of a relativistic degenerate gas.
(b) Using the Lane-Emden equation, show that the mass distribution in a polytropic star is given by eq. (4.12), and show that this yields eq. (4.13) for the total mass of a polytrope.
(c) Derive the expressions for the central density \( \rho_c \) and the central pressure \( P_c \) as function of mass and radius, eqs. (4.16) and (4.17).
(d) Derive eq. (4.18) and compute the constant \( C_n \) for several values of \( n \).

4.3 White dwarfs
To understand some of the properties of white dwarfs (WDs) we start by considering the equation of state for a degenerate, non-relativistic electron gas.
(a) What is the value of \( K \) for such a star? Remember to consider an appropriate value of the mean molecular weight per free electron \( \mu_e \).
(b) Derive how the central density \( \rho_c \) depends on the mass of a non-relativistic WD. Using this with the result of Exercise 4.2(b), derive a radius-mass relation \( R = R(M) \). Interpret this physically.
(c) Use the result of (b) to estimate for which WD masses the relativistic effects would become important.
(d) Show that the derivation of a \( R = R(M) \) relation for the extreme relativistic case leads to a unique mass, the so-called Chandrasekhar mass. Calculate its value, i.e. derive eq. (4.22).

4.4 Eddington’s standard model
(a) Show that for constant \( \beta \) the virial theorem leads to
\[
E_{\text{tot}} = \frac{\beta}{2} E_{\text{gr}} = -\frac{\beta}{2 - \beta} E_{\text{int}},
\]
for a classical, non-relativistic gas. What happens in the limits \( \beta \to 1 \) and \( \beta \to 0 \)?
(b) Verify eq. (4.25), and show that the corresponding constant \( K \) depends on \( \beta \) and the mean molecular weight \( \mu \) as

\[
K = \frac{2.67 \times 10^{15}}{\mu^{3/3}} \left( \frac{1 - \beta}{\beta^2} \right)^{1/3}.
\]  

(4.27)

(c) Use the results from above and the fact that the mass of an \( n = 3 \) polytrope is uniquely determined by \( K \), to derive the relation \( M = M(\beta, \mu) \). This is useful for numerically solving the amount of radiation pressure for a star with a given mass.
